MEDICINE

TEXT-BOOK

OF THE

PRINCIPLES AND PRACTICE

OF

MEDICINE

BY THE LATE

CHARLES HILTON FAGGE, M.D., F.R.C.P.

PHYSICIAN TO, AND LECTURER ON PATHOLOGY IN, GUY'S HOSPITAL; EXAMINER IN MEDICINE IN THE UNIVERSITY OF LONDON

AND

PHILIP HENRY PYE-SMITH, M.D., F.R.S.

FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS, PHYSICIAN TO, AND LECTURER ON MEDICINE IN, GUY'S HOSPITAL

Third Edition

VOL. I

LONDON

J. & A. CHURCHILL

11, NEW BURLINGTON STREET

1891

PREFACE.

THE First Edition of the present work, published in January, 1886, consisted of the MS. left by the late Dr Fagge, arranged and edited by the present writer, with numerous additions in the Second Volume, of which the most important were some sections on the Diseases of the Heart (by Dr Wilks) and all the chapters on Diseases of the Skin.

In the Second Edition, published in 1888, the whole book was revised: some parts (chiefly transcriptions of cases from other authors) were omitted, and the following chapters were added or re-written —those on Pyæmia, Enteric Fever, Febricula, Vaccinia, Rubeola, Actinomycosis, Peripheral Neuritis, Friedreich's and Thomsen's Diseases, Insular Sclerosis, and the chapter on Insanity by Dr Savage; while large additions were made to the sections on Diseases of the Heart, Pneumonia, Intestinal Obstruction, Diseases of the Liver, Anæmia, and Diseases of the Joints.

In the present Edition every page has been carefully revised; and, by occasional excision and more frequent compression, room has been made for such additions as the progress of medicine seemed to render desirable.

The Introductory Chapter has been re-written, and the Pathological Section which follows has been re-arranged and added to. The treatment of Enteric Fever and Diphtheria, and the pathology of Cholera and Ague, have been considerably expanded.

The great advances made in our knowledge of the anatomy and diagnosis of Diseases of the Nervous System led to considerable alterations and additions in this part of the book in the Second Edition, and similar though less extensive changes will be found in the present one.

The chapters on the Diseases of the Heart, which were something of a patchwork, have been revised and in great part re-written, so as to make as complete and homogeneous an account of this important subject as the writer's ability and the space which it seemed reasonable to assign to this section would allow.

The chapter on Phthisis has been condensed in some parts, and expanded in others. It had been already sent to press some time before the publication (at once too late and too early) of the method of treatment by inoculation introduced by the eminent discoverer of the essential nature of this disease, as well as (in all probability) of that of Cholera. The circumstances, however, of the announcement and practice of this method were such, and the disappointment of the

hopes at first existed has been so great, that the omission is perhaps not to be regretted.

The chapter on Influenza has been amplified from a historical compilation to a description based on experience of the epidemic of the last two years.

The additions and corrections in the sections on Diseases of the Alimentary Tract, of the Liver and of the Kidneys have been numerous, but on the whole less important than in the Second Edition. In the chapter on Diabetes an attempt has been made to present the problems involved from a point of view somewhat different from that taken by Dr Fagge, and perhaps more in accordance with recent physiological knowledge. The time, however, has not yet come for a satisfactory theory of this interesting and tantalising region of pathology.

The subject of Anæmia had been re-cast in the Second Edition, and the plan then followed has been adhered to, with the addition of some fresh clinical and pathological facts.

The chapters on Gout and Rheumatism, on Gonorrhœal Synovitis and Osteo-arthritis, and that on Rickets, have been expanded in several particulars.

Lastly, the section devoted to Diseases of the Skin, for which the writer was entirely responsible in the First Edition, has now been subjected to careful revision and correction, and such additions have been made as will, it is hoped, render it more complete than before.

New Indices, both of subjects and authors, have been constructed for this Edition, and, by a somewhat different arrangement of material, room has been gained for introducing the former one into the First Volume; so that each volume now contains a complete Index to the subject-matter of both.

I must again thank various correspondents who have favoured me with criticisms or references to new facts, and reviewers in home and foreign journals for their friendly and useful comments.

Special acknowledgments are due to my friend and colleague Dr L. E. Shaw, and to our late Medical Registrar at Guy's Hospital, Dr E. W. Goodall, for the help repeatedly given in statistical work.

Lastly, I must express my deep obligation to my friend Dr Cavafy, of St George's Hospital, who most kindly undertook the tedious task of reading the proof sheets, and to whose keen eye and accurate knowledge I am indebted for the correction of many errors.

P. H. PYE-SMITH.

HARLEY STREET;
July, 1891.

THE SPASMODIC NEUROSES

THE

PRINCIPLES AND PRACTICE OF MEDICINE

INTRODUCTORY CHAPTER

ἰατρεύει (ὁ ἰατρὸς) καθ' ἕκαστα.—ARISTOTLE.

Definition of medicine and of disease—Nosology: organic and functional diseases—Pathological anatomy and clinical characters as bases of nosology—Diagnosis—Symptoms and diseases—Symptoms and physical signs—General Ætiology: exciting and predisposing causes of disease—General Prognosis and Therapeutics—Arrangement of the present work.

MEDICINE—*Ars medendi*, *Ars valetudinis*—is the art of detecting, of relieving, and of preventing diseases.

Preventive Medicine, in its general object of preserving the health of the community, forms a separate branch best called HYGIENICS, and in its relation to government, is known as State Medicine. In its particular object of preserving individuals from diseases it will find its place in several parts of the present work under the name of Prophylaxis. It depends upon our knowledge of the causes and origin of each malady.

Curative Medicine, or THERAPEUTICS, includes not only the application of means which entirely remove the disease and without which it would continue, but also the far more frequent cases in which without directly overcoming the malady, its course is guided in the most favourable manner towards recovery, and those moreover in which, although the disorder cannot be arrested, its progress is retarded and its pain relieved. *La médecine guérit quelquefois, elle soulage souvent, elle console toujours.*

This art of mitigating the sufferings and in more or less direct ways saving the lives of the sick is, like all arts, empirical and individual; but it rests on a scientific basis: first on knowledge of the several disorders of the human body and of the natural functions from which they are deviations—Pathology; and, secondly, on knowledge of the various means, mechanical, physical, chemical, and vital, by which the morbid structures and functions may be influenced—Pharmacology, in the most extended sense of the word. Inasmuch as our knowledge on both sides is very imperfect, we depend on the result of experience to correct our conclusions and to regulate our future methods.

The practice of medicine, then, is an art, controlled by experience and guided by individual skill and insight, but resting upon the science of

pathology, or the natural history of diseases, as its principles—on an exact acquaintance with their origin, immediate and remote, their physiological course, and their natural termination.

The art of medicine has been compared to the art of watch mending, to the art of war, and to the art of education; but perhaps the best illustration of its scope and methods is the art of navigation, which depends on scientific principles, but consists in the application of science to individual and varying conditions, guided by natural acumen, and controlled by long experience.

The present work attempts to deal with both branches of Medicine, its principles and its practice. By an arbitrary but useful convention external injuries and diseases which are chiefly curable by operations are separately dealt with as Surgical Pathology and Therapeutics; and the diseases peculiar to women, as well as those incident to the eye and ear, are also treated of in modern times by special treatises.

DISEASE.—Many attempts have been made to frame a satisfactory definition of *disease;* but no better result has been reached than that it is the opposite of *health*, a derangement of the body in whole or in part, which causes pain or shortens life.

In truth both Disease and Health are incapable of precise definition, because they are not scientific terms. They are descriptive, popular, and subjective.

"Disease" is "discomfort." Whatever causes bodily uneasiness or whatever by experience will sooner or later cause it, whatever interferes with our bodily functions, whatever tends to death, is disease. Health is the opposite condition, of comfort, ease, and ability to eat, sleep, move, and perform the other functions of life.

Diseases have only this in common, that they all interfere with comfort or shorten life. There is no common cause for the pains of inflammation, of colic and of mechanical injury.

No line can be drawn between health and disease. Pathology is only physiology under various disturbing causes. Decay and death are as much physiological events as birth and life.

All diseases imply two things—an exciting cause, *quidquid irritans*, mechanical, thermal, chemical, parasitic, infective, or of unknown nature; and a reacting, living organism, *quidquid irritabile*. Stone in the bladder is not a disease; the disease is the reaction of the body. The severest injuries, the most violent poisons, produce no disease in a corpse.

There is a tendency after disturbance to return to the previous condition, if the equilibrium has not been too violently upset. This tendency has been called *Vis medicatrix Naturæ;* but there is no such force, and the so-called "efforts of Nature" often aggravate instead of curing the mischief. Our mortal bodies are not made to last for ever.

It is clear that if disease is not a single state nor the result of a single cause, it cannot be removed by any single method, or on any universal principle.

Hence all "Systems" of Medicine, like all "Universal remedies," are of necessity false. Iatro-mechanical and iatro-chemical schools, Brunonian and Antiphlogistic theories, Allopathy and Homœopathy, are all equally unreasonable; not wrong solutions of a scientific problem, but ignorant answers to an absurd question.

The art of medicine, therefore, is not concerned with Disease in the

abstract, but with separate diseases, with pains and discomforts, the cause, seat, and origin of which the physician seeks to detect, and, if possible, to cure in each case—*ἰατρεύει γὰρ καθ' ἕκαστα.*

NOSOLOGY.—Since diseases are of diverse nature, so that they are not mutually comparable, it is clear that a scientific classification of them is impossible. Hence there is little left of the importance formerly attached to Nosology, or the right nomenclature, definition, and arrangement of diseases.

It may, however, still be asked—and the inquiry is not without a practical bearing—whether in naming and classifying diseases we should do so according to their *causes*, their character as physiological *processes*, the *structural changes* they produce, or the *symptoms* by which we recognise them during life.

The first is the most satisfactory basis, for it is fundamental. When we define scabies as the effects of the presence of an acarus in the skin, or "dropt wrist" as paralysis from lead, we know the most important points at once, the leading indications for prevention and for cure. But our knowledge is far too imperfect to render an ætiological classification possible.

A pathological arrangement is almost as hopeless, for in many cases we are ignorant of the physiological derangements which are taking place, and the long list of "inflammations" includes very diverse diseases.

What has in modern times been called a pathological nosology is not one of processes, but of results. It is really based, not on morbid physiology, but on morbid anatomy. During the present century the utmost zeal has been devoted to the search for organic lesions in the dead body, and to tracing the relations between such changes after death and states of ill-health during life. Many anatomical lesions have been thus discovered, which were unknown to the physicians of former ages; and many of these can be recognised without difficulty by skilled observers, though the patient is unaware of their existence.

On the other hand, there is a not inconsiderable number of disorders which force themselves into notice by the pain or discomfort they occasion, and which may in some cases destroy life; and yet after death all the organs and tissues seem to have their structure unaltered even when they are examined with the highest powers of the microscope and by every chemical test that can be devised.*

At first sight it appears as though there were a fundamental distinction

* By many writers, the occurrence of functional diseases is altogether denied. They believe that if our inquiries could be carried far enough we should discover some morbid changes to account for every disorder or complaint, even the slightest. They say that they "cannot conceive" how any of the vital processes should fail to be carried on naturally so long as every part of the body retains an absolutely normal structure; and they seem to suppose that no further argument is needed to establish their opinion. But, as is well known, the history of philosophy is full of lessons which show how fallacious it is to assume that things are impossible because when submitted to the scrutiny of our faculties they seem to be inconceivable. The question is not whether an effect can arise without a cause, but whether the cause must necessarily be of one particular kind because we know of no other.

However, physiology suggests an analogy that may not perhaps be without its application to pathology; the case of muscular fatigue. This was formerly supposed to be the result of the consumption of contractile tissue in the performance of work. It is now known to be due to the accumulation in the tissues of those waste products which arise out of the contractile material so consumed. But the nerves and nerve-centres are also liable to exhaustion; and it seems not unlikely that the *neuroses*—as functional nerve disorders are called—may depend upon similar conditions.—C. H. F.

between *organic* or *structural* diseases attended with recognisable morbid changes, and *functional* diseases in which no such lesions can be found. But the progress of science is continually transferring maladies from the latter to the former class. So that the distinction between functional and organic disorders is, though convenient, not fundamental.

In both cases the "disease" is the *condition* of the living patient, the pathological *process*, the *derangement* of the functions, and this includes the "symptoms" (which are generally the most obvious phenomena in the living patient and which used themselves to be called diseases) and the anatomical lesion, if known, which underlies them.

Hence, as knowledge improves, what was a "disease" becomes a "symptom," and what was an anatomical lesion becomes the evidence of a pathological process. Dropsy, jaundice, paralysis, are terms which now denote only the first, not the final stage of diagnosis. Phthisis, which at first meant "wasting," afterwards meant a special anatomical lesion of the lungs, and now means the whole physiological process, including structural, functional, and symptomatic disorders which are the result of infection by a microscopic plant.

It is not necessary that every disease should be defined alike; in *scabies* the fundamental character is the presence of a special cause, in *aneurysm* it is an anatomical lesion, in *chorea* it is a series of disordered functions. Whenever a group of clinical cases can be traced to a single structural change, this should be regarded as the most essential element in the definition of the disease, and it should, if possible, furnish the name. But if the effects of several lesions are identical, so that they are clinically undistinguishable from one another, it is better to retain a common designation. Such an arrangement may be regarded as provisional, but it is likely to be needed for many years to come.

DIAGNOSIS.—Until we have traced a disease to a definite organic lesion we can seldom be sure that cases which seem to be identical are really so; and upon their real identity depends all certainty of knowledge as to their cure.

Again, until we know the origin of the structural lesion we cannot tell how to guard against its production, *i. e.* how to prevent the whole process which we call the disease.

The process by which we give a name to a case is one of analysis; and in some cases we can carry this process further than in others. A complete diagnosis, such as "variola," "syphilitic iritis," "scabies," includes recognition of the characteristic symptoms of the anatomical lesion in its seat and structure, and of the origin of the whole morbid process. Nevertheless, to say that a patient has "hepatic ascites," though an incomplete diagnosis is sometimes more accurate than to say that he has "cirrhosis of the liver," for we cannot always exclude perihepatitis, or cancer, or gummata. To define a cerebral case as one of "hemiplegia" is better than to call it "softening of the brain," if the lesion is but little less likely to be a clot of effused blood, or a tumour, or an abscess. Yet there are cases in which we can be sure that cirrhosis of the liver, or that softening of the brain is present; and it is obviously better to name such cases according to their respective lesions.

The diagnosis of "hemiplegia" or of "ascites" is a provisional but not a wrong diagnosis: the phenomena which are commonly spoken of as sym-

ptoms are parts of the disease to which they belong, no less than the lesion, or the specific cause, or whatever else is taken as its main characteristic. It is true that, when they afford the means by which we infer the existence of a hidden morbid change, they bear to it the relation of effects to a cause; but this only shows that the term symptom is a relative one. So long as we are unable, either during life or after death, to discover any cause for a set of clinical phenomena, they certainly are not symptoms, for they indicate nothing. There can be no symptom until the disease of which it is a symptom is discovered. As the process of analysing a case or a group of cases advances, the name which we apply is rightly changed at every step; and each "disease" becomes in its turn a "symptom" of the disease which succeeds it. Itching was once hardly distinguished from the itch; afterwards, when the characters of the eruption of scabies were made out, itching was looked on as a symptom, and the eruption was the disease; now that the *sarcoptes* has been discovered, the eruption is itself reduced to a symptom.

If, however, the analysis is always arrested at a certain point, it is absurd to say that the ultimate fact in such cases is "only a symptom." So far from hesitating to classify clinical symptoms as diseases when we are unable to trace them to their causes, it is to be wished that we had a more complete supply of suitable names denoting functional disturbance. It is probable, as Dr Moxon argued in the 'Guy's Hospital Reports' for 1870, that a good "clinical nomenclature" would be quickly followed by a great advance in our knowledge of functional disorders.

Even when we understand the whole pathology of a case, and when the clinical phenomena which characterise it are rightly called symptoms, the distinction between them and the anatomical lesions is often arbitrary. Thus, in acute tuberculosis, if the ophthalmoscope discovers a tubercle in the choroid membrane of the patient's eye, it is called a symptom; but the disease itself (anatomically) is but a multitude of precisely similar tubercles. So, again, the enlarged liver of mitral disease, the nodes of syphilis, the swollen joints of rheumatism belong in strictness to the pathological anatomy of these several complaints. Nor, if we would be logical, can we stop even here; the same thing must be said of all cutaneous eruptions, down to the rose-rash of enteric fever.*

On the other hand, in the case of a functional disorder, to speak of the clinical phenomena as symptoms is really to reduce the "disease" itself to a mere name.

Practically, however, we agree to call all indications which help us to a diagnosis, symptoms, whether they respect structures or functions.

SYMPTOMS AND SIGNS.—Symptoms, so defined, naturally divide themselves into two distinct classes. Some of them are "subjective;" that is, they are appreciable by no one but the patient, so that our knowledge of them rests solely on his statements. Others are "objective;" that is, they can be directly observed by other persons; indeed, they can be investigated when the patient himself is unconscious.

Now, subjective symptoms are open to fallacy. They can often be feigned by one who desires to deceive. Moreover, their severity depends

* In that part of 'Ziemssen's Cyclopædia' which is devoted to the exanthemata, the appearances seen on the skin are in fact described in some instances (but not in all) apart from the "symptoms," and under the head of "anatomical changes."

upon the nervous susceptibility of the individual in whom they occur: a hearty labouring man will take no notice of a pain which would drive a delicate lady to her bed for weeks. In the former case one must be careful not to overlook, in the latter not to assume, the presence of disease. Yet constant attention must be paid to subjective symptoms, for they often yield information which can be obtained in no other way.

The physician elicits objective symptoms by examining the patient's body with hands, eyes, and ears. Until the time of Auenbrugger, Corvisart and Laennec, he could do little more than feel the pulse and look at the tongue. Then came the discoveries of percussion and of auscultation, which gave to the diagnosis of diseases a precision undreamt of before. It was natural that those who introduced the new methods should endeavour to mark their value by giving a special name to the indications afforded by them. And thus it became usual to speak of "physical signs" as opposed to "symptoms." In reality, however, the distinction is untenable. A raised temperature, an internal squint, albumen in the urine—are all "physical signs," no less than a cardiac murmur or a dull percussion-note; and small crepitation is as much a symptom as rusty sputa. Lastly, it is misleading to call a particular symptom "pathognomonic," as if it bore so close a relation to the disease that, whereas all the rest of the symptoms afford only presumptive indications of its presence, this one proves it absolutely.

ÆTIOLOGY.—Our knowledge of the *causes* of diseases is, as a rule, exceedingly fragmentary and imperfect. In many instances there is little difficulty in perceiving that an illness has been preceded by some definite change in the outward circumstances of the patient, or in the action of some vital organ: he may have been chilled by exposure to cold, he may have eaten unwholesome food, he may have been over-excited or over-fatigued; and one of these conditions is then called the "*exciting cause*" of the disease. But, on further consideration, it appears that people often go through weather no less inclement, indulge their appetites as foolishly, have their mental and bodily powers strained as much, without being attacked by the same, or indeed by any disorder. We now have no alternative but to assume that some other cause has also been in operation. This may act in two ways: it may combine with the exciting cause to produce the disease in him who falls ill, or its influence may affect those who remain well, by counteracting the operation of the exciting cause. But in practice we generally assume that all causes of this kind have a positive rather than a negative action; and we are therefore accustomed to group them together under the name of "*predisposing causes.*"

It is, however, important to note that some apparently predisposing causes of diseases do not operate in either of the ways just mentioned. A complaint may affect persons at a particular age, merely because at that age they are more exposed to the action of the exciting cause. Thus scalds and burns are particularly frequent among young children; and scalds of the throat from drinking hot water from a kettle scarcely occur in grown-up persons. On the other hand, young adults are much more liable to break their limbs than are old men. Such differences arise, not from a predisposing influence of one period of life, nor from a counteracting influence of another period, but from infants being ignorant of the effects of heat, and from men at their prime being obliged to work under exposure to accidents. So, again, if general paralysis and locomotor ataxy and many

other diseases of the nervous centres are more frequent in men than in women, the reason may be that more men than women come under the operation of the exciting causes of these complaints, such as overwork, sexual excesses, and the like.

The most obscure of predisposing causes are those which are commonly included under the term "idiosyncrasy." It is well known, for example, that in certain persons nettlerash is produced by strawberries, and that in others the odour of cats excites asthma. In such cases the exciting cause is obvious, and we must regard as predisposing causes the conditions, whatever they may be, which lead to its effect upon one person and not on another. But of these conditions we are altogether ignorant.

In some cases predisposition seems to be unnecessary. The presence of the acarus in the skin is the sole and efficient cause of scabies, and needs nothing more than a normal human skin to produce the lesions and the symptoms which make up the disease scabies. Yet even here it appears that certain abnormal conditions, as typhus, and perhaps other febrile states, counteract the ordinary operation of the irritant. Again, contact with another is the indispensable precedent of every case of variola, yet here again a previous attack renders the organism "refractory" to the normal operation of the contagion. That grown people are little susceptible to measles is probably explained by most of them having already had it.

If we attempt to classify diseases by their causes, we may put first those which are due to the presence of animal or vegetable *parasites*, both such as act mechanically by their presence as irritants, and those minute parasitic fungi which multiply excessively and fill the whole organism that they invade with swarms of microphytes.

Next may be placed, from an ætiological point of view, those disorders which are the direct result of *chemical poisons*, the paralysis caused by lead, the delirium of belladonna poisoning, the tremors of workers in mercury, the fatty degeneration caused by phosphorus. In these cases the effects are very uniform in character, and depend in degree upon the dose of the poison, with little reference to the recipient.

Next we may put *dietetic* diseases, as cirrhosis of the liver and delirium tremens, caused by spirit drinking. Here, although the cause is true and constant, its effect depends upon something in the individual, for some drunkards die rapidly from the effect of intemperance on the brain, others more slowly from its effect on the liver, and others again escape both.

The action of *cold* is still less constant. Exposure to weather produces in one man rheumatic fever, in another bronchitis, in a third pleurisy or pneumonia, so that we cannot predict what disease will be produced by the cause, or whether any at all.

The remaining "causes" of disease are so vague and uncertain in their action that we must suppose that some peculiar combination of conditions is needful to produce the morbid effect, and that of one or more of these conditions we are ignorant.

When we cannot assign any probable cause for a disease we often call it "idiopathic" or "spontaneous;" meaning that so it appears to be, until its true ætiology is ascertained.

A small ætiological group of diseases consists of those which are the result of *defect of formation*, as cyanosis from congenital disease of the heart.

A larger one includes those which depend upon various *senile degenera-*

tions of the tissues and organs. But many of these changes which occur as the result of ordinary wear and tear in most persons above a certain age may also be found in those much younger, in whom excessive strain has prematurely produced the same effects.

On the whole it may be said that the cause of diseases is more confidently assigned by the patient than by the physician.*

When degenerative, developmental, contagious, parasitic, toxic, and traumatic diseases are excluded, there remains by far the greater number of the real origin of which we know nothing.

Even in these cases, however, their natural history—the conditions of age, sex, occupation, geographical distribution under which they most commonly occur—is of much interest. Such knowledge is often a useful help in diagnosis, and may one day lead to more complete conclusions as to ætiology. So that under this head such details are appropriately placed.

It is in reference to the prevention of diseases that a knowledge of their ætiology is of the greatest practical use, but indirectly it often has an important bearing upon their diagnosis and their cure. The process of analysing the clinical symptoms, which constitutes the diagnosis of a case, often stops short of tracing it to a definite anatomical lesion; and we are unable by that path to reach any basis for a sound plan of treatment. Every circumstance in regard to possibly exciting or predisposing causes of the patient's illness may then be of great value in helping us to treat it successfully.

PROGNOSIS.—Before we attempt to modify the progress of a disease by treatment we have to ascertain what is its natural course when undisturbed by our art, so that we may know as certainly as possible whether the remedies which we use are effectual. It is this study that enables us to give what is termed a *prognosis* or forecast of the case to the patient himself or to some near relative, a part of our duty which may be of the highest importance, and in which our credit and reputation are more concerned than even in treatment. In some cases, indeed, the prognosis is of such a character as almost to make any further services to our patient unnecessary. We may be able to declare that the disease will quickly and safely pass off, without tendency to relapse, and without risk of its leaving any ill effects behind it. A case in point is an attack of shingles in a child. Or we may have to say that the malady is one which must inevitably prove rapidly fatal in spite of every effort that can be made to arrest it. Such a prognosis, for instance, must be given in many cases of apoplexy, of aneurysm, and of tetanus, and in almost all of cancer. But, as a rule, our prognosis applies, not so much to the natural and undisturbed course of the disorder, as to that which we believe it will take under the most judicious treatment we can devise.

Prognosis is not only concerned with the favourable or unfavourable event of the disease, but also with its probable duration, the chances of its return, and the possible or probable complications against which it is most important for the physician to be forewarned.†

* As Sir William Gull well put it: "in disease as well as in astronomy, savages explain, science investigates."

† 'Guy's Hospital Reports' (1887), vol. xliv, p. 59.

TREATMENT.—Therapeutics, or the art of curing diseases, depends much more upon the physician's knowledge and skill, and much less upon drugs, than is supposed by the laity. In few cases can a malady be certainly and directly "cured" or arrested by a given method, as soon as the diagnosis has been made; and in still fewer is medicine powerless for the comfort and welfare of the patient.

In some diseases no treatment is needful. All that is important is that they should be recognised, and the patient assured of his safety.

In others the only reasonable treatment is expectant; that is, to refrain from meddling without knowledge, and to watch carefully for opportunities of helping favourable and relieving unfavourable symptoms.

In others, again, treatment is strictly rational, *i. e.* it consists in employing mechanical, chemical, or physiological means for directly meeting an injurious condition. Such is the treatment of laryngeal dyspnœa by opening the trachea, of poisons taken into the stomach by chemical antidotes and by emetics, of high temperature by cold affusion. In the same way we treat iritis by belladonna, dropsy by diuretics, typhlitis by opium, and uterine hæmorrhage by ergot.

There remain a considerable number of cases in which, without our being able to see the physiological action of the means that are used, we are able to modify or arrest the process of a disease by treatment which depends entirely upon experience of its value. As examples, may be mentioned the relief given by external warm applications in most inflammatory states, the benefit of counter-irritation, the use of purging in certain cerebral affections, of colchicum in gout, of tarry applications in psoriasis, of iron in chlorosis, and of mercury in syphilis. These last so-called specific medicines have doubtless a physiological action which, if known, would explain their practical value; and in some cases we can perceive a doubtful connection between their known properties and their therapeutical effects. But at present their action is "special," peculiar, and inexplicable.

Arrangement of the present work.—As above explained, no scientific classification of diseases is possible, inasmuch as they are incommensurable objects. The most practically convenient arrangement is the best. For the reasons already given, the anatomical lesion is, when ascertained, the most definite and satisfactory basis of nomenclature and classification; when this fails, we generally name and group diseases by their most important clinical features, or in accordance with the organ most obviously affected; and these associations are often more important than affinities of pathology and causation. Thus scabies is more usefully studied along with other forms of dermatitis than with ringworm or hydatids, and phthisis goes more naturally with bronchitis and pneumonia than with lupus.

In accordance with general practice, from which it is inconvenient to deviate except for some sufficient reason, we shall take first among diseases those which have been long known as specific fevers affecting the whole body, and running a more or less constant and limited course.

Next, still following the traditional order, will come the diseases of the brain and nervous system, then those of the chest, and afterwards affections of the abdominal viscera.

Lastly, we will for convenience place certain more or less general diseases, the true pathology of which is undetermined, which are neither

strictly local nor yet specific fevers. They are—scurvy and other disorders accompanied by anæmia and hæmorrhage, which may provisionally be regarded as primary *hæmatoses;* rheumatism, gout and other "idiopathic" and multiple affections of the joints (*arthroses*); and the numerous and complicated disorders which affect the skin and its appendages.

In each section we shall more or less closely follow the same order, dealing first with the name and history of the disease; then with its clinical characters, course, and complications; next with its anatomy and pathology, its ætiology and natural history, and its diagnosis from other diseases. Lastly will come its prognosis and prophylactic, palliative, or remedial treatment.

Before, however, we begin the study of the several specific fevers, it will be well to devote a few preliminary chapters to certain pathological processes which are common to them and to many of the local diseases to be afterwards described.

These are contagion, fever, inflammation, pyæmia, and the formation of new growths. Other general pathological processes, as anæmia, dropsy, embolism, and the various forms of degeneration, will be better considered afterwards with the diseases in which they are most important.

INFECTION

Οὐρῆας μὲν πρῶτον ἐπῴχετο καὶ κύνας ἀργούς

Βάλλ', ἀιεὶ δὲ πυραὶ νεκύων καίοντο θαμειάι.
HOMER.

Transmission of diseases—Contagion and miasm—Theory of infection—Contagium vivum—Microbes—Their origin and life—Their exclusive action in producing specific diseases—Their mode of action—Immunity from contagion—Protective inoculation—Modes of transference of miasmata and contagia—Theory and practice of disinfection.

FROM an early period it has been observed that certain diseases are contagious, or "catching," by direct contact with the sick person, or by means of clothing or buildings which transmit the *materies morbi*. When actual contact took place, the disease was called *contagious;* when it was transmissible by the air, it was given the wider name of *infectious*, and the vehicles of transmission were called *fomites*.

These diseases frequently spread so rapidly that they become *epidemic*, and thus have devastated whole kingdoms and changed the course of history.

They have been, and still are, called *specific* diseases—partly from the special and peculiar course which they run, unmodified by the accidents of diseases produced by injury or cold or local inflammation—partly because each one was believed to be produced by a single definite efficient cause, the supposed *virus* or *contagium* or *materies morbi*, the presence and nature of which is now in many cases demonstrated.

There are, however, other "specific" toxic disorders which must be distinguished from the general contagious diseases. These are:—

(1) The effects of chemical poisons. Mercury, arsenic, lead, phosphorus, morphia, strychnia, when absorbed into the lymph and blood so as to reach the tissues, produce definite and constant effects, specific in their locality and symptoms, and pointing unmistakably to their "specific" origin. But these effects are strictly limited by the dose of the poison, and they are not transmissible from one person to another.

(2) The effects of certain organic poisons the chemical nature of which is imperfectly known. Such is the venom of snakes, a nitrogenous and probably a proteid compound; the albuminoid principle of jequirity seeds, called *Abrin*; and the remarkable ferment discovered by the late Dr Wooldridge, the injection of which produces instant coagulation of the blood in the portal vein.

(3) The effect of certain products of decomposition, causing septic poisoning: these are nitrogenous but alkaline, and probably compound ammonias. They have been called *ptomaïnes* or cadaveric alkaloids, *leucomaines* and *toxines*.

In all these cases the poison is a chemical compound, and acts in proportion to its strength; moreover, the morbid conditions produced are not transmissible.

(4) We must also separate certain diseases which are truly contagious and

which depend on the presence of living organisms, but which are only local in their effects and do not produce any general physiological disorder. Examples are scabies and ringworm.

There remain the specific contagious febrile diseases, in which the contagion consists of a swarm of living organisms, *microbes*, which multiply in the host, set up a disturbance of the whole body and render it for the time a focus of fresh infection.

This group of diseases has been divided as follows:

(1) *Contagious diseases proper.*—Each of these maladies owes its origin to a *virus* or *contagium*, derived from a person already suffering from it, or from one of the lower animals. Among these are the Exanthemata, Typhus, the Plague, Mumps, Whooping-cough, and Glanders.

(2) *Miasmatic diseases.*—These are caused by a contagium which is derived from the soil, or from the water, or from the air of a place, independently of the occurrence of similar illness in another person. Ague is the chief example of this group.

(3) *Miasmatic-contagious diseases.*—This group, which is acknowledged by all German observers, is little recognised in England.* The typical examples are Enteric fever and Cholera, diseases which are undoubtedly spread by human intercourse, and which are usually, if not always, traceable to previous cases, but which are nevertheless believed not to be directly communicable from one sick person to another. Liebermeister's hypothesis is, that patients give off a contagion which is inoperative until it has passed through further stages of development outside the human body, and that these changes may be taken as converting it into a kind of *miasm*.

The distinction is a convenient one for the present, but will no doubt become obsolete with increasing knowledge.

Theory of infection.—Contagia often appear as fluids; this is the case, for example, with the vaccine lymph, with the contents of smallpox vesicles or pustules, with the nasal discharge of glanders, and probably that of measles, and with the faucial secretion of diphtheria. Chauveau in France, and Burdon Sanderson in England, have demonstrated the fact that the activity of these fluids belongs, not to chemical compounds dissolved, but to minute particles suspended in them. They have shown, for example, that when vaccine lymph is allowed to diffuse into distilled water through a porcelain diaphragm, the diffused liquid is incapable of conveying cow-pox by inoculation.

That contagia are "particulate" is therefore clear. The next point is as to the nature of the particles. For a long time the dominant view was that they were inorganic, or at least devoid of life, that their properties were essentially chemical, and that they acted "catalytically" or after the manner of *ferments*. On the ground of this analogy the epithet "zymotic" was coined, and applied to the whole class of infective diseases, and the contagia were called *microzymes*.

But ferments are of two kinds, chemical like pepsin, and perhaps snake's venom, or particulate like yeast; and the particles of yeast are living

* The epithet "miasmatic-contagious" was proposed by Henle in 1840. He, however, only had in his mind the circumstance that smallpox, scarlet fever, typhus and other maladies often seem at first to break out epidemically, as though they might have been caused by a miasma, whereas afterwards the individual cases afford clear evidence of contagion. But Liebermeister and other recent writers have assigned a fresh meaning to the term "miasmatic-contagious," and have limited its application to a special class of maladies.

organisms, so that there can be little doubt that the particulate contagia are living organisms of exceedingly minute size.

Moreover, in two infective diseases—Relapsing fever and Anthrax—the *constant presence* of such organisms was several years ago positively demonstrated. To these may now be added: Tuberculosis, Lupus and Leprosy, Glanders, Erysipelas, and several forms of Septicæmia in the lower animals. The cases of Enterica, Scarlatina, and certain other specific diseases are more doubtful; while in some, as Typhus and Plague, no characteristic microbe has yet been discovered.

The conditions which justify our regarding a given organism as the material cause, the *contagium vivum*, of a given malady may be stated as follows:

(1) The malady must have such distinct and constant features, whether clinical or anatomical, as shall enable it to be identified.

(2) The microphyte must be itself distinguishable from others by its size and shape, its staining properties, but above all by its mode of propagation in "a pure cultivation" (*i. e.* artificially separated from other organisms) and by the form and colour of the colonies it produces.

(3) The organism thus identified must occur in the blood or tissues—not merely on the surface, cutaneous or intestinal, but below the epithelium, in the lymph-spaces or blood-vessels—in every case of the disease in question.

(4) It must not occur in the human body except in cases of the particular disease in question. It may, however, conceivably exist in other animals without giving rise to the same pathological symptoms; or in air or water—as it exists in the test-tubes and plates of "pure cultivations," and in whatever media convey the contagion from one person to another.

(5) When a pure cultivation of the organism is introduced into the blood and tissues of an animal, the phenomena, clinical and anatomical, of the disease in question must be reproduced.

These conditions in all their rigor have been satisfied in the case of Anthrax, and with scarcely less abundant proof in that of Relapsing Fever.

The micrococcus of Erysipelas has also been established as the *contagium vivum* of that disease by good evidence.

In Variola and Vaccinia micrococci are present, but they have not been proved pathogenic by experiment. In Pneumonia several microphytes occur, but not constantly, and which, if any, is the true pathogenic organism is still uncertain. The micrococci of Gonorrhœa and of ulcerative Endocarditis are constantly present, and probably pathogenic, but they are less certainly identified, and the proof is incomplete. The bacilli of Enteric fever, of Diphtheria, and the so-called comma-bacillus of Cholera, are still the subjects of controversy as to identity, constancy, and pathogeny.

The theory that specific infection depends on the transference of living microscopical vegetable organisms is in harmony with the fact that so many other processes which bear a clear analogy to specific infection are constantly associated with the presence of microbes. Lister, in a paper read before the Pathological Society in 1877, established that the lactic acid fermentation, or souring of milk, is essentially dependent upon what he termed the *Bacterium lactis;* and Pasteur had previously shown that the alcoholic and the butyric fermentations have a similar origin. So, again, that putrefaction is set up by certain bacteria (or *saprophytes*) is now certain; the success of

Lister's method of treating wounds is nothing less than a demonstration that they remain aseptic only so long as the organisms which induce decomposition can be kept at a distance.

The organisms concerned in these various processes differ remarkably in size, and therefore in the readiness with which the microscope reveals them. The *Torula cerevisiæ*, or yeast plant, which brings about the alcoholic fermentation, is made up of rounded cells which develop by budding, and have a diameter of $\frac{3}{10,000}$ or $\frac{4}{10,000}$ of an inch. The *Bacterium lactis*, which causes the souring of milk, consists of oval bodies, arranged in pairs or sometimes in chains, multiplying by fission, and measuring at the most $\frac{1}{20,000}$ of an inch, that is, being no larger than the granules which are contained in the cells of the torula. Consequently, as Lister argues, there is nothing improbable in the supposition that yet other organisms may exist which may be as much smaller than the *Bacterium lactis* as it is smaller than the torula. Heydenreich aptly remarks that, were it not for the length of the spiral threads which form the microbe of Relapsing fever, it would in all probability have escaped detection; rounded or oval bodies not exceeding in diameter the breadth of the *spirillum* would be almost invisible with the highest powers of the microscope.

The following are the most important parasitic microphyta. They all agree in not containing chlorophyll:

1. Moulds (*Mucorini*, *Hyphomycetes*, *Schimmelpilze* of Nägeli). These are long-branched filaments, which form numerous spores. To the pathologist they have little interest, but one species is sometimes found lining the interior of dry vomicæ in the lungs (*Aspergillus fumigatus*). Other forms cause certain cutaneous affections, as ringworm.

2. Budding fungi (*Saccharomycetes*, *Blastomycetes*, *Sprosspilze* of Nägeli). These consist of rounded or oval cells, which give off buds, and may form beaded threads. To this group belongs *Oidium albicans*, the parasite of thrush.*

3. Fission-fungi (*Schizomycetes*, *Spaltpilze* of Nägeli). These are small bodies, which multiply by fission, with or without production of spores.

α. *Spherical bacteria* (*spherobacteria* of Cohn, *coccaceæ* of Zopf, *micrococci*) are exceedingly minute. They sometimes cohere in pairs (*diplococci*), sometimes in chains (*streptococci*), and sometimes in heaps (*staphylococci*), and sometimes they are aggregated into masses held together by a jelly-like material (*zooglœa*). *Sarcinæ* are micrococci arranged in square or cubical packets, the result of fission in different planes.

β. *Bacilli* (*desmobacteria* of Cohn) are cylindrical rod-shaped bodies, which sometimes remain united after they have undergone fission, so as to form threads of considerable length.

γ. *Rod-shaped bacteria* (*microbacteria* of Cohn) are smaller than bacilli. They are often slightly constricted in the centre, or dumb-bell shaped.

δ. *Spirilla* and *spirochætæ* are spiral filaments (*vibriones*, *spirobacteria* of Cohn), having a well-marked corkscrew motion.

By Billroth rod-shaped and spherical bacteria were associated together under the name of *coccobacteria*. By other authors the bacteria and bacilli are combined, and, from a morphological point of view, this is well justified. But these names are all descriptive only, and not indicative of botanical

* Another (*Saccharomyces capillitii*) has been recognised on the hairy scalp and elsewhere on the skin. Two other remarkable pathogenic fungi are found in cases of Madura foot in India (*Chionyphe Carteri*) and of Actinomycosis.

relations. A more important distinction is between microphytes, which form endogenous spores, like *Bacillus anthracis*, and those which multiply by fission only.

It can be easily understood that there is often great difficulty in distinguishing micrococci from lifeless granules of organic or inorganic matter. An oscillating motion is of no significance, for it depends on vibrations transmitted from without to the liquid in which the granules float. Brunonian movements also affect dead particles. Bodies which subdivide or which cohere into chains may safely be set down as organisms. Irregularity in size is almost sufficient to show that the granules which differ among themselves are not micrococci; but uniformity in this respect affords no positive proof that organisms are present. The power of resisting liquor potassæ is evidence of a cellulose investment of the protoplasm being present, *i. e.* of the microbe being vegetable.

It is often convenient to be able to refer to them under a common name, without specifying their exact characters; and for that purpose the word *microzyme* was suggested by Béchamp and adopted by Sanderson. *Microphyte* is perhaps a better term. *Microbe* is the one used by Pasteur and the French school.

Microphytes are classified as *aerobic* and *anaerobic* by Pasteur, according as they grow in contact with oxygen, or protected from the air.

An important distinction is that made by Flügge, into *septic* (*saprogenic*) or putrefactive microphytes, *zymogenic* or fermentative, *chromogenic* or pigment-forming, and *pathogenic* or productive of specific diseases.

Zopf carried Nägeli's and Billroth's doctrine of the "pleomorphism" of the schizomycetes to its utmost limit. But more critical biologists admit variation in form of one and the same organism only within certain narrow limits. This was first proved by Lankester in the case of *Bacterium rubescens*, a chromogenic microphyte, since named *Clathrocystis roseopersicina* by Cohn ('Quart. Journ. Mic. Soc.,' 1876).

There is no reason to believe that chromogenic microphytes can be cultivated into zymogenic, or septic into pathogenic. The assertion by Buchner that the common *Bacillus subtilis* of infusion of hay was interchangeable with the Bacillus of anthrax and *vice versâ*, has been refuted by Klein. Pathogenic bacteria, however, may undoubtedly suffer diminution of their malignancy (or may acquire it in intenser degree) by being passed through a series of hosts. This is the explanation of Jenner's vaccination, for there is little question that the cow-pox is variola passed through successive generations of cattle. And on the same principle Pasteur has succeeded in "attenuating" the virus of anthrax, of so-called "chicken cholera," and of hydrophobia, so as to protect against the unmodified disease by inoculation, or, as he calls it, "vaccination," with the attenuated contagium.

Contagious pus.—Mr Hutchinson has repeatedly expressed the opinion that the "contagious inflammations' (as he terms them) differ essentially from the specific fevers, and that they are conveyed from one person to another by leucocytes or living pus-corpuscles, and not by microzymes. The instances he enumerated in the discussion of the Germ Theory held by the Pathological Society in 1875, were Gonorrhœa, Erysipelas, purulent Ophthalmia, and Porrigo. The points on which he relied in support of his views were chiefly two; first, the frequency with which some of these diseases occur apart from any apparent origin in contagion; and secondly,

the fact that the severity of the inflammatory process in each disease varies widely in different cases, and may be modified at will in experimental inoculations, as when gonorrhœal pus is applied for the cure of pannus. This last argument seems, however, to be met by the fact that as much may be said of some maladies which are typically specific; and although erysipelas often appears to be directly caused by exposure to cold, a similar origin can sometimes be traced for diphtheria.

Lister's observations on the lactic acid fermentation teach an important lesson in regard to this question. One would certainly have thought that the souring of milk, which so constantly occurs when that fluid is left standing for a few hours in warm weather, must depend upon causes which are in operation everywhere, and that any microbes concerned in the process would be devoid of specific characters. But Lister found that although the *Bacterium lactis* appears to be universally present in dairies, it is scarce elsewhere: milk which has been boiled may be exposed to the air in ordinary rooms for half an hour at a time, but while other bacteria and filamentary fungi may develop, it will rarely, under such circumstances, become curdled and sour, nor will it contain the *Bacterium lactis*. Is it not probable that though the occurrence of common inflammation favours the development of erysipelas or diphtheria, yet access of specific microphytes is the essential factor in the ætiology?

There can be little doubt that pus is contagious by virtue of the presence of certain micrococci which have been described by Ogston and cultivated by Rosenbach, Garré, and other pathologists under the title *Staphylococcus pyogenes aureus*. This appears to thrive out of as well as in the body, and to be very widely, almost universally, distributed. Without going so far as Hüter in denying that suppuration ever takes place except as the result of access of staphylococcus or allied microphytes, we may say that this is probably true of all contagious and specific pus.

In the pus of Gonorrhœa and of Erysipelas, recent research has shown the constant occurrence of specific microphytes, described as *gonococcus* and *streptococcus* respectively.

Spontaneous origin of contagia.—Some physicians, of whom the late Dr Murchison was one, used to believe that certain typically specific diseases sometimes arise *de novo*, independently of contagion or of any virus derived, directly or indirectly, from previous cases. No doubt all such diseases must have had a commencement at some period of the world's history, just as animals and plants must have had a beginning; but we are only concerned as physicians in the question whether specific diseases are started afresh in the world as it is; and the same answer must be given as to the theory of spontaneous generation of animals and plants. When the origin of an outbreak of a contagious malady has been investigated with sufficient care, it has often been traced in the most conclusive manner to a previous case, perhaps at a great distance, from which it may have been derived in some indirect and unexpected way. Moreover it is worthy of notice that particular instances, of which no satisfactory explanation can be given, occur in the case of smallpox—of which a spontaneous origin was always admitted to be most unlikely—no less than in that of diphtheria, or typhus, or enteric fever, which were once supposed to be frequently so generated. Sir Thomas Watson cites Dr. Gregory as having stated that, of the cases admitted into the Smallpox Hospital in his day, not one in twenty could be referred to any known source of infection.

We may therefore absolutely reject the doctrine that any of the specific diseases ever result from such causes as overcrowding or starvation; or even from the inhalation of sewer gas which contains no specific virus.

It is, however, another question whether the microphytes of an infective malady, after escaping from patients, may not sometimes go on multiplying for long periods of time, and spread to distant localities, before they again penetrate into the human body. In the miasmatic-contagious diseases it seems probable that such a process of development always occurs. In some also of the strictly contagious diseases there is reason to believe that it is a stage in their development. Moreover, some of these maladies are derived from the lower animals, as favus from cats, glanders from horses, and anthrax from cattle.

Course of infection.—When the virus of an infective malady enters the human body, an interval occurs during which the health of the patient remains apparently undisturbed; this is called the period of *incubation*. In some diseases, as in smallpox, it is almost always of the same length. This fact is of great importance, because it enables us to say, when a person has been exposed to infection, that after the lapse of a certain number of days, if not already attacked, he is safe, and may mix with other people without risk to them. It is, in other words, the foundation upon which rests the practice of *Quarantine*. The duration of the incubation of each specific disease has accordingly been studied with care. The only cases in which it can be positively determined are those in which there has been but a single exposure to contagion; but others, in which the exposure (though repeated) began only a few days before the patient's illness showed itself, are valid as proofs of a short incubation; and others again, in which the exposure ceased many days before he fell sick, are valid as proofs of a long incubation. It seems now to be established beyond all doubt, that whereas the incubation of each specific disease is fixed within certain limits for the majority of cases, there are yet some cases in which the limits are overstepped. Thus scarlet fever, which commonly has an incubation of nearly a week, sometimes breaks out within twenty-four hours of the first exposure to its infection. It is undoubtedly hard to reconcile this fact with what is otherwise a reasonable explanation of the interval of incubation, namely, that it is occupied by the multiplication of the virus within the body. According to Nägeli, schizomycetes commonly double their numbers in from twenty to twenty-five minutes at the temperature of the blood. Lister found that the *Bacterium lactis* took about an hour in completing the process of growth and subdivision. In diseases, such as syphilis, in which a local lesion precedes the development of constitutional symptoms, the virus may be supposed at first to multiply itself locally (in syphilis, within the hard chancre) and not to enter the blood in any considerable quantity until a later period. There is evidence that in the rare instances of the syphilitic poison being communicated by vaccination, the resulting chancre has yielded an infective material within ten days afterwards. On the other hand, an unfortunate case once occurred at the Charité Hospital of Berlin, in which variola was conveyed to a patient by the operation of skin-grafting, the graft having been taken from a person who happened to be in the incubation-stage of the disease. This seems to show that from a very early period the whole of the skin contains the virus, which can have reached it only through the blood; and if so, the same thing must occur likewise in the exceptional

instances in which smallpox is inoculated into the skin at a particular spot. In such cases, however, there is developed a "primary" or "mother-vesicle" which precedes the general eruption by some days. It therefore seems to be very unlikely that in any disease the multiplication of the virus during the incubation remains altogether limited to a local lesion, although it may be more active there than elsewhere.

Such speculations touch a question which is still discussed, namely, whether in specific diseases generally the various characteristic local lesions or *foci* are to be regarded as sources of the infection-blood or as consequences. Thus in diphtheria, do microzymes first settle upon the mucous surface of the fauces, or upon whatever part happens to be the seat of the diphtheritic process, and afterwards penetrate its tissues and enter the blood? Some have even thought that in enteric fever the blood is infected from the intestinal lesions; and Liebermeister endeavoured to prove that in yellow fever there is primary hepatitis. But in typhus and in relapsing fever we have diseases to which such a view cannot apply, for there are no characteristic local lesions; and, in the exanthemata, fever and other general infective symptoms precede the cutaneous eruptions by a considerable interval of time. Moreover, in diphtheria itself there is a well-marked tendency for the throat to be affected even when the virus has originally been deposited elsewhere and may therefore be supposed to reach the fauces through the blood.

Physiological action of the microphytes.—With regard to the mode of production of the pyrexia and of the other symptoms of specific diseases by their contagia we know at present scarcely anything. The microbes, in multiplying so enormously as they do, must of course abstract nutrient materials from the blood and from the tissues; and as fungi they must also absorb much oxygen from the blood and lymph. The idea of a "struggle for existence" between these organisms and the tissues of the host was carried out in detail by Nägeli. He argued that when a person is exposed to contagion, his taking the disease or resisting it depends probably in part upon the number of microbes which enter his body, in part upon the condition of his blood and of his tissues at the time. Everyone who has experimentally cultivated the lower organisms knows that when more kinds of organisms than one are present, a slight change in the composition of the fluid in which they are placed may completely alter the result, enabling a microbe which previously was weaker to outgrow that which had been the stronger. And so Nägeli supposed that slight alterations in the state of the blood may greatly favour or oppose a contagion in the competition on which it enters. Moreover, some remarkable observations of Metschnikoff, first made on a minute crustacean, but afterwards repeated on frogs, seem to show that bacteria introduced into the blood either kill the leucocytes, or are themselves absorbed and digested by these guardians of the invaded organisms ('Vichow's Archiv,' Bd. xcvii).*

The analogy of the various fermentations suggests (as Lister has remarked) that, besides appropriating the materials for their own growth, microzymes may also cause further disturbance by catalytically decomposing other substances of which they make no use.

Again, it is certain that, while living, these minute organisms must be

* See also Mr Bland Sutton's 'Introduction to General Pathology' (1886).

constantly giving out or excreting waste products, and these, though excessively small, would, when accumulated by an enormous number of microbes, become a large dose of probably poisonous materials for the host—which may be called "toxines," analogous to the ptomaines produced by putrefactive bacteria. Lastly, it must be remembered that the mere physical results of immense swarms of these microbes may possibly lead to blocking of lymph-channels, or starvation of ganglion-cells, or suffocation of living protoplasm.

Protection.—Can we explain by the "germ theory" of specific infectious diseases the remarkable fact that most of them protect the organism which has once survived their attack from future invasion? There are apparent exceptions to the rule, and the degree and duration of the protection varies for each malady; but most of the specific contagious diseases occur only once in the life of the same individual; and perhaps none of them is entirely devoid of a protecting influence. We must suppose that in the course of each disease the blood or the tissues undergo such a "sterilization" that they no longer afford the conditions requisite for the development of its peculiar microphytes. There are obvious objections to the notion that human beings in general are born provided with a number of different materials which serve no known purpose but that of affording nutriment to the various contagia, in case of their invasion. Nor is it easy to suppose that the leucocytes, when once they have got the better of the invading swarm of bacteria, are so habituated to the attack that they gain an easy victory over any subsequent irruption of the same species, while yet they are as unable as at first to deal with any other species; and that they transmit to their descendants the same power of destruction, with the same limitation, down to a more or less distant generation.

Some remarkable experiments by the late Dr Wooldridge appear to throw light upon this curious problem. He found that by cultivation of a certain bacillus in a neutral fluid the latter became so "exhausted," or at least so altered, that it would no longer support a cultivation.

In some diseases, as in relapsing fever and in diphtheria, the duration of the protective action is perhaps no greater than is just sufficient to prevent the patient from reinfecting himself. In others it lasts during the whole of life. Indeed, an interesting question is whether it may not, in some cases, be transmitted from parent to child. As is well known, the exanthemata often rage with extraordinary virulence when they are introduced into communities that have been free from them for a great length of time. Other explanations of this fact are possible; but the reason may be that the victims come of a stock which has not for many generations been exposed to the contagion. It would be very interesting to investigate to what extent differences in the severity of a specific disease, attacking various individuals under the same conditions, in countries where it is always more or less prevalent, may depend upon whether one or both of the parents of the several patients had had that disease in childhood, or at least before the patients themselves were born. It might even happen, in the case of a malady which commonly affects adults, that successive generations should in turn succumb to it, in consequence of the continued absence of such an inherited protection.

Prevention of infective diseases.—These considerations seem to render

doubtful the advisability of attempting, even if it were practicable, to eradicate infectious diseases from this or any other country, and then to keep them off by a system of quarantine. Sir Thomas Watson gave to such a scheme the weight of his authority. But we cannot "stamp out" scarlatina and cholera as we can anthrax or pleuro-pneumonia in cattle—by destroying each patient as soon as he is attacked; and sooner or later each disease would be sure to find an entrance, and it would probably commit unheard-of ravages among a population long free from it. It is even doubtful whether we ought to teach the public to look upon the maladies in question as in a special sense "preventable." They are certainly not so much so as those which result from over-indulgence in food and drink, from exposure to cold, or from syphilis.

A more promising method of combating infection seems to be that of which we have an illustration in the practice of vaccination. And there is reason to hope that in the future this method may be far more widely extended than hitherto. Pasteur has demonstrated the fact that the virus of anthrax can be so diminished in intensity that it is no longer fatal to cattle, and that after inoculation with this modified or attenuated virus they are no longer susceptible of the disease. The same success attended him in dealing with the contagious disease of poultry (called by a misnomer *choléra des poules*); and recently he has applied a similar method to the prevention, and practically to the treatment, of hydrophobia. We may hope for future advance in the same method, which has made smallpox a preventable though unhappily not always a prevented disease.

There is, lastly, another method by which plague and typhus and ague have been almost banished from England—improvement of the circumstances of life, by which either the organism is better able to resist the invasion of the virus, or the conditions have been rendered unfavourable for the multiplication and even the survival of the virus itself.

Method of transference of contagia.—We have still to consider how the microzymes of contagion or of miasm gain access to the human body.

When suspended in the air, they probably penetrate into the capillaries of the lungs through the stomata of the pulmonary alveoli; they make their way through the mucous membrane of the mouth or the fauces by the mucous crypts; and they enter the blood or the lymph through wounds or abrasions.* After being swallowed they penetrate the mucous membrane of the alimentary canal.

In describing the invasion of the several specific diseases, we shall find evidence that their contagia differ much in the readiness with which they pass the natural barriers of the skin and mucous membrane.

Contagia have traditionally been divided into those which are "fixed" and those which are "volatile." As we have seen, it is certain that none of them are gases or vapours, and that they all consist of solid particles of exceedingly small size. But is it possible that the particles in question are capable of escaping with the water which evaporates from liquids or from moist solid surfaces, and of diffusing themselves in the air?

Nägeli seems to have conclusively demonstrated that this is impossible. He performed a series of experiments with V-shaped tubes connected together. In one bend he placed a liquid suitable for the growth of microzymes; another bend he filled with sand saturated with a putrefying

* It has been supposed that examples of such a mode of infection are sometimes afforded

liquid. Even when air was drawn through the apparatus he found that no microzymes passed from one tube to the other. And on theoretical grounds he shows that no other result could have been anticipated.

We have been accustomed to think that the breath of persons suffering under an infective disease is apt to be highly charged with the virus, and that the offensive odours exhaled from his moist skin, or from his excreta, may be highly dangerous. According to Nägeli all such notions are erroneous; he even declares that the presence of fœtor is generally a sign that the substances which give rise to it are still moist, and are therefore incapable of setting free any microzymes which they may contain. But it is obvious that some parts of an infected mass may remain covered with fluid, while others have already undergone desiccation.

Of course it is not disputed that liquids in which the microzymes of a specific disease are floating may convey it to healthy persons. Indeed there are some maladies, such as hydrophobia and syphilis, which seem scarcely to be communicable, except by a process of inoculation, the poison being introduced into a bite or a wound, or a crack in the skin. And diphtheria is often spread by the direct transference of mucous secretion from one individual to another. It is also to be remembered that the punctures made by insects may sometimes be the means of conveying the virus; cattle, for instance, are liable to be infected with anthrax by gadflies.

Moreover, there is the clearest evidence (although Nägeli denies it) that certain specific diseases are transmitted by means of liquids which are swallowed. So far as drinking-water is concerned, these facts will be stated in the chapters on enteric fever and cholera. Still more interest attaches to the remarkable facts which have recently been made out in this country as to the conveyance of the poisons of enterica and of scarlatina by means of milk, and also of tubercle by means of food. It is probable that, even in water, the specific mycrozymes multiply in the interval between its contamination and its reaching the human stomach. But there can be little doubt that milk affords far more favourable conditions for their growth; for Lister proved in his experiments with this fluid that (unlike even Pasteur's solution) it was capable of serving as a pabulum for almost any kind of microscopic organism. Once only did he meet with a bacterium that could not live in it.

With these important reservations, however, Nägeli is probably right in maintaining that infection generally occurs in a very different manner, namely, by means of microbes which have undergone desiccation, and which rise into the air and remain suspended in it in the form of a fine dust: the particles, perhaps, even more minute than those which become visible in the track of a sunbeam. How little influence gravitation has in causing the subsidence of such particles is well illustrated by the facts that volcanic dust from Vesuvius and from Krakatoa is carried in the atmosphere to distant parts of Europe, and that the trade-winds convey dust across the Atlantic Ocean from America.

The conditions under which microzymes thus become suspended in the air must be discussed separately for miasmata and for contagia.

(1) In the case of a *miasm*, at least any miasm which consists of microbes

by the so-called "surgical scarlet fever," which so often breaks out in children after operations; but, since Dr Goodhart has shown, in the 'Guy's Hospital Reports' for 1879, that its occurrence is not prevented by the strictest "antiseptic" treatment, there appears to be more probability of its arising in the ordinary way.

which live in earth, the first condition of its development is the presence of water in the interior or upon the surface of the ground, and the presence in this water of substances fit to serve as pabulum for the microbes. Further, it is necessary that the level of the water should vary from time to time, so that particles of the soil itself, or the stems and the leaves of plants growing upon it, should undergo desiccation, and should receive deposits of microbes, also in a dry state. So far as the miasm of ague is concerned, there is no necessity for supposing that it is derived from far below the surface of the ground, or for invoking the assistance of any force beyond that of the wind, for the purpose of carrying up the dried microbes into the air. But if any value is to be attached to the observations which Pettenkofer and others have made at Munich with regard to enteric fever and to cholera, microbes concerned in the propagation of these "miasmatic-contagious" diseases must be assumed to come in some cases from the soil at a depth of several feet. The conditions which may be supposed to render this possible are very carefully argued out by Nägeli. In the first place, he thinks that in the ground-water which saturates a porous soil below a certain level, the growth of microphytes is likely to be especially active towards the surface of this water. Hence the slightest fall in the level of the water must cause an abundant settlement of microbes upon stones, sand, and fragments of clay and humus, which come into contact with air as soon as the water recedes from them. In this subterranean atmosphere he conceives that currents are produced by various causes: changes of temperature, changes of pressure, winds, and lastly, the suction action of warm air into the interior of houses having deep foundations. Such currents, he thinks, may easily carry away the dry microbes, especially if there is no precipitate of colloid matter from the water, to make them adhere closely to the substances on which they are deposited. A further condition, at least so far as concerns their escape into the air above, is that the superficial layers of the soil through which they must pass should not be damp, and should not be covered with a uniform carpet of vegetation.

(2) The microbes of a *contagium* doubtless leave the body mainly in the fluid excretions, the saliva, the urine, the fæces, and the sweat. They may also be attached to the cuticle which is constantly being shed from the surface; in the case of scarlet fever and in that of smallpox this mode of diffusion of the poison is believed to be of great importance. In either case their escape is due to no process of "elimination," and is of no advantage whatever to the patient. Indeed, the microbes which find their way out of the body are probably altogether insignificant in number, when compared with those which remain in the blood or in the tissues, and undergo destruction there. The microbes which adhere to fragments of cuticle are already dry; those which are contained in fæces, in urine, or sweat, must undergo desiccation before they can reach the air. Nothing is more favourable to this than the soaking of linen or other fabrics with any of the infected secretions. The microbes remain upon the surface of the cloth when it dries, and are afterwards shaken off by the slightest movement. It is a most natural circumstance, therefore, that washerwomen and their families should be very liable to attack by contagious diseases; and instances in which infection has been traced to the hanging out of clothes to dry are readily explicable if one considers how imperfectly the process of washing is often performed.

Persistence of contagia.—One cannot state with any approach to certainty, how long a patient remains capable of infecting others after his recovery from a contagious disease. Perhaps his secretions cease to contain microphytes as soon as the pyrexia is at an end. This at least appears to be the natural inference from the observations which have been made of a rapid disappearance of *spirillum* from the blood in relapsing fever. But for a considerable time afterwards fresh portions of infected cuticle may be continually shed.

Contagia sometimes adhere with great tenacity to the walls of an apartment which has been tenanted by a patient suffering under an infective disease, and to bedding or clothes which have been used by him. Nägeli mentions that at Munich several masons fell ill with smallpox after scraping the ceiling of a room in which smallpox cases had been treated six or seven years before, and which had then been whitewashed. Sir Thomas Watson relates the following instance: A house in which several persons had been attacked by scarlet fever was left empty for a year. When the family returned, a drawer in one of the bedrooms resisted for some time attempts to pull it open. A strip of flannel had got between the drawer and its frame, and had made the drawer stick. This piece of flannel the housemaid put playfully round her neck. An old nurse who was present, recognising it as having been used as an application to the throat of one of the subjects of scarlet fever, snatched it away and burnt it. The girl, however, soon sickened with the disease. Woollen substances seem to afford the most favourable conditions that can be imagined for the preservation of microzymes in a state of activity, short of their being enclosed in sealed glass tubes. By the hygrometric properties of such substances, contagia adherent to them may probably be prevented from undergoing too complete a desiccation, while they are at the same time protected from currents of air.

Destruction of contagia.—Steps must always be taken to prevent a person affected with a contagious disease from being a source of danger to others. But what can really be done in this direction is not always clearly apprehended.

During an illness the utmost care should be taken to hinder the contagion from being carried away from the sick-room by means of attendants, or in the patient's excreta, or upon the linen of his bed or body, or in any other way. In all probability its escape into the open air through windows or chimneys is of no consequence.

At this time, it is impracticable effectually to disinfect the patient himself or his surroundings, and therefore that the attempt should not be made.

The patient, after recovery, and the nurses also, should be most carefully disinfected; minute pains should be taken to prevent clothes, books, and other articles from conveying contagion; and the sick-room with all its contents should be thoroughly purified before healthy persons are allowed access to it.

The measures which should practically be adopted to ensure these objects seem to be the following:

1. The patient himself must be isolated in a separate room or suite of rooms, which, if possible, should be at the top of the house. An intervening passage, of which the windows can be opened, is, of course, an advantage. Ventilation should be carefully attended to, and it is well that there should be a fire, so as to maintain a draught up the chimney. The doors should be

kept closed, and outside them there should be hung an old sheet saturated with a liquid solution of carbolic acid or chloride of lime, and never allowed to become dry. The addition of glycerine to this liquid is probably advisable. It seems to be useless to expose vessels containing carbolic acid in the sick-room itself, or to scatter chloride of lime upon the floor.

Those who nurse or wait upon the patient should not be allowed to enter other parts of the house, and, if possible, such persons should be chosen for this duty as have already had the disease. The medical attendant should take care by ablutions, by change of clothing, and by exposing himself freely to the open air after each visit, to avoid carrying contagion abroad. One is often asked whether the father of a sick child should be allowed to continue his work in an office or chambers, so as to come into contact with others. Probably if he avoids coming near the patient and takes a walk when he leaves the house in the morning, no appreciable risk is run, so long as he himself remains well.

All curtains, carpets, and padded chairs, all articles of wearing apparel in cupboards or in drawers, all unnecessary articles of furniture of whatever kind, should be removed from the sick-room before the patient is placed in it, because their presence will make unnecessary difficulties afterwards. Only such books or toys should be allowed as are not too valuable to be burnt when they are done with. Any food or drink which the patient or the nurse may leave should be thrown away. Cups, plates, and spoons should be put in boiling water before they are allowed to go back to the kitchen; but, as far as possible, it is well to keep the same articles from day to day in use in the sick-room, and to wash them there.

2. All the excreta of the patient should be rendered innocuous by the addition of some disinfectant.

The experiments of the late Dr Baxter, recorded in the sixth volume of the new series of Mr Simon's 'Reports to the Privy Council,' have shown that few at any rate of the substances commonly used really possess the power of destroying contagia. He employed *carbolic acid*, *sulphur dioxide*, *potassic permanganate*, and *chlorine*. Each of these substances was added in definite proportions to vaccine lymph, and a series of vaccinations were performed with mixed liquids upon children, one arm of the child being inoculated with the lymph supposed to be disinfected, while the other arm was at the same time vaccinated with lymph that had been diluted with water to a corresponding degree. The results which he obtained were: that with chlorine and with potassic permanganate there is no security for effectual disinfection short of the presence of free chlorine or of undecomposed permanganate in the liquid, after all chemical action has had time to subside. In the case of sulphur dioxide the criterion of success is that the liquid should be permanently and strongly acid; in the case of carbolic acid that it should contain at least 2 per cent. by weight of the pure acid. It is further necessary that the disinfectant should be thoroughly incorporated with the liquid; there must be no solid matters capable of shielding the contagious particles. Other effectual disinfectants are thymol, and other aromatic compounds, fluosilicate of soda and—in some respects the most valuable of all—corrosive sublimate.

A point on which Baxter lay stress, as Nägeli had also, is that the addition of disinfectants in too small quantities may do harm instead of good. Probably all the substances that can destroy contagia are also antiseptic agents; that is, they can prevent putrefaction. And it appears

that they are capable of doing this even when present in too small a quantity to disinfect. At first sight this seems contradictory. But it is not really so; for Baxter showed, that when an infusion to which (for example) 2 or 3 per cent. of carbolic acid has been added fails to putrefy, the bacteria in it nevertheless remain alive, and that they begin to multiply if a little of the infusion is mixed with another liquid that can afford them pabulum. Now, it is this power of affecting other liquids, and not its capacity for undergoing putrefactive changes itself, which is really comparable with pathological infectiveness. And it is a well-ascertained fact that (except, perhaps, in the case of glanders) the occurrence of putrefaction in a liquid deprives it at once of whatever contagious property it may possess. Thus, if a disinfectant is added in too small quantity, it may easily happen that its action is precisely the opposite of what is intended: by preventing putrefaction, it keeps the contagious microbes alive.

3. For the purpose of wiping off discharges from the nose or the mouth of the patient, pieces of rag should be used, and they should be burnt immediately afterwards. The sheets and body-linen should be placed in a tub of water as soon as they are changed, and they should of course be washed apart from those of other persons. It is usual to soak them in a weak solution of carbolic acid or in diluted Condy's fluid; but this is probably of little use. The really important point is that they should be submitted to the action of water at a high temperature. The safest plan is to boil them in a copper. But there is reason to believe that a degree of heat far below 212° may be sufficient. Thus, Davaine found that the virus of anthrax diluted with water was destroyed in five minutes by a temperature of 131° F., and Baxter that even dry vaccine was rendered inert in thirty minutes by a temperature of 185° or upwards. There is no doubt that in the dry state contagia resist heat much better than when they are suspended in water.

The linen worn by the nurse should be treated in the same way as that of the patient. The dress should always be made of a material that will bear washing.

4. At the end of the illness, when it is believed that the patient is no longer giving off contagion from his body, he must be carefully washed with ordinary soap. Special pains should be taken to cleanse the hair thoroughly. He should then be dressed in clothes none of which have been in the sick-room, and should be moved into another apartment. Similar precautions should be taken whenever a nurse or an attendant goes away, at whatever period of the case.

5. The room which has been occupied by the patient during the disease must be carefully disinfected before healthy individuals are allowed to occupy it.

In the first place, moveable articles that cannot be washed should, if possible, be exposed to dry heat. The temperature required for the destruction of contagia in the dry state appears to be considerably higher than that which suffices when they are suspended in a fluid. It varies with the length of exposure, the time needed being longer in proportion as the temperature is lower. Some hospitals for infective diseases have hot-air chambers, erected for the purpose, in which there is no difficulty in raising the temperature, even in the centre of a flock-bed, to 220°, 240°, or 300° F. There seems to be no doubt that this must be completely effectual in killing any kind of virus.

The next step is to destroy any microbes that may be floating in the

atmosphere, or adhering to the sides of the apartment, or to the furniture. With this object the fumes of sulphur or chlorine gas may be used. All the openings into the room, chimney, windows, and doors, must be made as air-tight as possible. A good plan is to set fire to a few ounces of bisulphide of carbon in an iron pan supported over a pail of water. Or from a quarter to half a pound of brimstone broken into pieces may be placed in the pan and live coals used to ignite it. The room is then closed and left so for several hours.

Finally, the ceiling should be scraped and whitewashed, the walls should be re-papered, the floor should be thoroughly scrubbed, and all the paint in the room, as well as the furniture should be very carefully washed.*

* Since the first edition of this book appeared many excellent treatises on the subject of microphytes and contagion generally have appeared in English. Of these may be particularly mentioned Dr Klein's 'Micro-organisms in Relation to Disease' (2nd ed., 1889), Dr Crookshank's 'Introduction to Practical Bacteriology' (1886), Mr Watson Cheyne's original papers and his translation of German essays on 'Bacteria in Relation to Disease' (published by the New Sydenham Society, 1886), the chapters on contagion and on bacteria in Professor Hamilton's text-book of pathology (vol. i, 1889), and in the admirable 'Student's Manual of General Pathology' by Dr Payne (1888).

FEVER

Febris: calor præter naturam.—GALEN.

Pyrexia—Thermometry—Clinical course of pyrexia—Hyperpyrexia—Theory of fever—Possibly beneficial effect of pyrexia—Idiopathic and symptomatic fever—Raised temperature without fever—The physiological stages of fever—Concomitant phenomena of pyrexia: nutrition: pulse: respiration: muscles—Subnormal temperature.

AMONG the varied effects of diseases there is, perhaps, none which is more commonly met with—and certainly there is none which is more important—than PYREXIA or FEVER. It is not surprising, therefore, that the ancient writers recognised this condition.

But it is strange that in modern times scarcely any attention was paid to it until recently. The specific fevers were studied; but of the febrile state, common to them and to inflammatory disorders generally, little notice was taken. An increased action of the heart was considered as its chief characteristic.

It would be difficult to overstate the value of an advance which was made early in the second half of the present century, by the introduction into medical practice of the clinical thermometer, as a direct and simple method of determining the presence or absence of pyrexia. This was not, indeed, a novelty. About a hundred years previously the instrument had been used by Boerhaave and by his pupils Van Swieten and De Haen; and De Haen, who was a physician at Vienna, had discovered the striking facts that in ague, during the cold stage, the temperature of the blood is increased, and that the temperature of the body may sometimes rise after death. Hunter made many thermometric observations, and Dr John Davy published extensive tables of temperatures in animals and in man, under varied conditions of age and climate, in health and in disease. But when in 1850–51, Traube and Bärensprung independently called attention to clinical thermometry, the practice was new. From that date Wunderlich, of Leipzig, devoted infinite pains to the study of temperature in all diseases. In this country the practice was soon adopted by Parkes, Ringer, Aitken, and a host of others; and we may safely assert that it will never again be abandoned.

Methods.—The use of the thermometer in clinical practice requires considerable care, if the results are to be relied on as being even tolerably accurate. The instrument is most commonly placed in the axilla, although there are other and often more suitable places, of which we shall speak presently. Now, the temperature which we want to ascertain is that not of any part of the surface, but of the deeper structures of the body, an inch or more below the level of the skin. To determine the surface temperature of any region is quite another, and a most difficult matter. Instruments called surface-thermometers have been constructed, with the receptacle for the mercury of such a shape that one side of it can lie flat on the skin while

the other side is protected with a non-conducting material, so as to diminish as much as possible any loss of heat from it. But to cover up any part of the surface of the body is, of itself, to raise the temperature above that at which it previously stood.

When a thermometer-bulb is placed deeply in the axilla, the fold of the groin, or elsewhere, the mercury goes on rising until it indicates a temperature corresponding very closely with that of the body, at the same distance from the skin as that at which the instrument is placed, and it is uncertain what length of time such an observation may take for its completion. A great deal depends upon whether the parts were closely in contact before the thermometer was introduced. Thus, if the patient is lying on one side in bed, one should always choose the more dependent of the two armpits, since it will give a fixed temperature far more quickly than the other. When a thermometer has once risen to its full height in the axilla, a second one placed in the same spot immediately afterwards will rise to the same point in from three to five minutes. But it is a very different matter in a thin person, or if the arm has been separated from the chest, so that the axilla has contained air, and perhaps a fold of underclothing. It must then itself rise through several degrees before it can bring the thermometer to a stationary point; and the length of time required for this to take place will vary indefinitely, according as the circulation of blood in the peripheral parts of the body is active or otherwise. When the skin is hot and turgid, as in scarlet fever, a comparatively short period will suffice; in the cold stage of ague, and still more during the collapse of cholera, it is doubtful whether an axillary temperature can ever be relied on. It is to be observed that this uncertainty is independent of any defect of sensitiveness in the instrument which happens to be employed.

There is reason to believe that the scientific value of thermometric observations made in this country is impaired by the comparatively short space of time devoted to them. It is commonly thought that from three to five minutes suffice for this purpose; and it must of course be admitted that a temperature above the normal, however quickly obtained, is a positive fact, which from a practical point of view can never be worthless. Dr Bäumler, however, has shown ('Brit. Med. Journ.,' 1864) by direct experiments that, even when all ordinary precautions are taken, it may easily happen that too low a reading by ·3 to ·8 of a degree Fahrenheit is arrived at, if the thermometer is withdrawn from the axilla at the end of five minutes. He found that from eleven to twenty-four minutes are required to give an absolutely trustworthy result. Liebermeister goes still further: for even of a period of from fifteen to thirty minutes, he does not say more than that it suffices for the majority of cases. The rule which he lays down is that the instrument should be observed to remain stationary for several minutes before it is removed. In practice, however, this is impossible, and in ordinary cases we may with due precautions be satisfied that after five minutes only a small fraction of the total increase of temperature fails to be recognised.

It is essential in placing the bulb in the axilla that no clothes should be allowed to remain in contact with it, and that the skin should grasp it firmly. If there be any perspiration, the hollow must first be wiped dry. The arm should then be folded across the chest, and the hand may be made to take hold of the opposite arm, while the opposite hand supports the elbow of the side on which the thermometer is.

When, from emaciation or any other cause, the parts do not meet

closely round the instrument, some other region should be selected. In the case of infants and young children, the *groin* is better adapted than the armpit, for the fat is more abundant at that age, and children who resent the arm being held will often allow the thigh to be kept close to the abdomen without moving.

The *mouth* is a suitable place, if one can depend upon the patient's keeping it constantly closed and breathing entirely through the nose. The bulb may be placed either beneath the side of the tongue or at the back of the cheek. Dr Bäumler found that from nine to eleven minutes sufficed to raise it to a fixed point there.

Of all localities for thermometric observations, the *rectum* is theoretically the best, and though it cannot be often used in practice, yet it should be chosen when there is doubt as to the accuracy of an axillary or oral observation; and it is particularly suited for children and for old people. An important advantage is the saving of time, for from three to six minutes are enough to give a result of scientific value. Consequently it is advisable to make use of the rectum whenever much depends upon the exact temperature at the moment, or when an ice-bath may perhaps be required. And it is to be noted that a rectal temperature can be taken with a registering thermometer while the body is immersed in cold water.

By far the most rapid method of taking the temperature of the body accurately is for the patient to hold the bulb of the thermometer in the *stream of urine* when emptying his bladder. The glass and mercury are rapidly heated, for the cooled fluid passes at once away. The method is most applicable for taking the temperature in the evening before going to bed, and also for ascertaining the presence or absence of pyrexia when a patient is going about or visiting his physician. (See a short paper by Dr Oertmann in 'Pflüger's Archiv,' Bd. xvi.)

When, after the withdrawal of the instrument, the index has been read, it is common to dot down the result on a sheet of paper ruled for the purpose. Observations are repeated at regular intervals twice a day, every two hours, or even oftener, and each successive reading is recorded in a similar manner. Lines are then often traced from dot to dot so as to form what is termed a "chart." It is, however, important to remember that the result is artificial. However short may be the intervals at which the thermometer is applied, there is no reason for supposing that the patient's temperature moves straight upwards or straight downwards from one point to another. And when the intervals are long, as when the instrument is employed only twice in the twenty-four hours, there is not even a probability that the dots marked on the chart each day represent respectively the true maximum and the true minimum. We shall, indeed, presently see that in disease as in health there are, as a rule, certain daily fluctuations, the temperature being generally highest at a particular hour in the evening and lowest in the morning. But even when the observations are made just at those times, there is no security that the rule is observed in that special case on any one day; and it is always highly probable that between each pair of observations there may have been two or three or even several ascents and descents of the temperature which altogether escape notice. Some therefore prefer to make no chart at all, but to place the figures in two vertical lines, one for the morning, and the other for the evening.

The course of pyrexia is naturally divisible into certain periods or stages,

which, however, vary greatly in length in different diseases. First comes the "pyrogenic" or "initial" stage; during its continuance the temperature rises more or less steadily, the rise being interrupted, if it extends one, two, or more days, by the daily fluctuations already alluded to. When it is of short duration or when the rise is at first rapid, there is commonly a shivering fit or *rigor*—the first and important indication of a severe disturbance of the central nervous system.

The second stage is the *fastigium;* in it the temperature reaches its *acme* or highest point; but, not infrequently, since this stage may last for several days or even two or three weeks, it is characterised (independently of the daily fluctuations) by a series of irregular slight ascents and descents, so that the highest point or one very near it may be touched again and again at longer or shorter intervals.

The third stage is that of *defervescence*, during which the temperature falls again to normal. Sometimes, however, it is separated from the second stage by an intervening period, called by Wunderlich the "amphibolic" stage, in which irregular exacerbations and remissions are observed. Or, again, there may at the end of the second stage be a marked rise of temperature termed by Wunderlich the *perturbatio critica*. The third period, that of defervescence, is sometimes protracted, sometimes short and sudden. In the former case the pyrexia has been said to end by *lysis*, in the latter by *crisis*. The rule is to speak of a critical termination only when the fall to a normal temperature is completed within thirty-six hours; but sometimes the third stage begins with a slight and gradual descent, which after two or three days ends in a crisis. When defervescence is rapidly accomplished, it is generally accompanied by profuse sweating and sometimes by an abundant flow of some other secretion.*

After defervescence the temperature often remains for some days slightly subnormal. It is also less stable than in health, being easily disturbed by slight causes, so that, for example, a rise of one or two degrees is apt to follow the first solid meal.

It is often convenient to be able to express in general terms the degree of pyrexia without giving the actual temperature. And for this purpose Wunderlich's classification may be adopted; it is as follows:

1. *Subfebrile*, temperature in axilla 99·5°—100·4° Fahr.; or 37·5°—38° C.

2. *Slightly febrile*, temp. 100·4°—101·3°; or 38°—38·5° C.

3. *Moderately febrile*, temp. 101·3°—102·2° in morning; 101·3°—103·1° in evening; or 38·5°—39° C. in morning; 38·5°—39·5° C. in evening.

4. *Decidedly febrile*, temp. about 103·1° in morning, about 104·9° in evening; or 39·5° C. in morning, 40·5° C. in evening.

* That Wunderlich and others thus have adopted the term "crisis" is perhaps to be regretted. For it is scarcely possible for anyone who is familiar with the medical writings of the ancients to shake off the remembrance of earlier mystical notions which formed an important part of their teaching. When we come to describe the specific forms of fever, we shall find that each of them has a more or less definite duration, and that one can often confidently look forward to a future day, a week or two distant, as that in which defervescence is likely to take place. But this is very far from what the Greek writers or even some moderns have meant by critical days, their idea being that all fevers, without reference to differences between them, ought to come to an end on certain days rather than on others, so that when one critical day was passed, the disease might be expected to run on until the next critical day occurred. The whole of the doctrine in question is without foundation.—C. H. F.

5. *Hyperpyretic*, temp. approaching 107·6° or even higher (42° C.).

A less elaborate but possibly as useful a nomenclature is :—Feverish, 99·5°—101° Fahr. Febrile, 101°—104°. High fever, 104°—106°. Hyperpyrexia above this.

We must, however, bear in mind that in the case of children fever is set up very easily ; an evening temperature of 105° may be due to comparatively trifling causes ; and on the following morning the thermometer may not rise far above the normal point. So, again, sensitive women sometimes show a "highly febrile" condition, when the result proves that no apparently adequate cause for it has been present. On the other hand, in old people the temperature is apt to be below what one would have expected from the gravity of the case. So that high temperature in children is often of no ill omen, while even slight pyrexia is serious in an elderly patient. At what point the term *hyperpyrexia* should begin to be used is somewhat uncertain ; but it is generally understood to mean such a temperature as is sufficient of itself to endanger life if long continued. Cases in which the thermometer rises to 109° or 110° (43·5° C.) are very exceptional, and most observers think that they are invariably accompanied by severe and alarming symptoms. Just before the death of a patient from tetanus Wunderlich obtained a temperature of 112·55° (44·75° C.) ; and this perhaps remains the highest recorded point that has certainly been reached.

Paradoxical temperatures.—A few instances have, however, been recorded in this country which, if they can be relied on, seem to show that far higher temperatures have occurred, not only without being followed by death, but sometimes without being attended with serious symptoms.

The first case of this kind was observed by Mr J. W. Teale ('Clin. Soc. Trans.,' 1875) in the person of a young lady, who by a severe accident had several ribs broken, and afterwards suffered from great tenderness over the dorsal vertebræ. Two months later her temperature was one day taken at 110° ; and afterwards the index of the thermometer was on four occasions buried in the bulb at the top of the instrument, at a point above 122°. Sometimes these extraordinary temperatures were taken in the axillæ, sometimes between the thighs, or even in the rectum. She was at first in an exceedingly weak state, but she gradually improved and regained fair health.

Other examples of "paradoxical temperatures," as they have been called, have been met with by Dr Donkin ('Brit. Med. Journ.,' 1879). His first case was that of a nurse who was recovering from enteric fever, when the thermometer was found one night to register 110°. Afterwards very high temperatures were repeatedly taken, on a single occasion one of 111·6°, yet no symptoms could be discovered accompanying this reading beyond a feeling described by the patient as one of "flushing" or "rushes of heat." But perhaps the most singular circumstance of all was the evanescent character of this pyrexia, if it deserves that name ; once the thermometer rose to 107·2° in the right axilla, whereas five minutes later it stood at 98·6°. In the mouth a temperature of 106° was once observed. It does not appear that the instrument was ever held *in situ* while such extraordinary results were being obtained, but the patient's hands were watched, and the idea of imposture was present. Seven other cases are cited by Dr Donkin, all but one of them being in females.

In 1879 a remarkable instance of this kind occurred in Guy's Hospital under Dr Moxon. The patient, a girl of 22, had been in the ward for phthisis

during ten months, when on the evening of July 25th her temperature was taken at 107·4° and about an hour aftewards at 110·8°. She appeared to be suffering somewhat from dyspnœa. On the following morning the thermometer stood at 99·8°. During the next few months the most extravagant variations of temperature were recorded. On one occasion Dr Mahomed obtained simultaneously a reading of 102° in one axilla, and of about 114° in the other axilla, one of 107° in the mouth. On changing over the instruments the highest temperature was attained in the axilla where it had before been lowest, that of the mouth being now 104°. Another day a small registering thermometer gave 102·6° in one axilla, while another one in the other axilla gave 109·4°; but directly afterwards, when two large instruments without indices were used, and when the patient's arms were held all the time, the temperature stood at 103° on each side. Dr Mahomed noted that the skin always felt moist and of the ordinary temperature, even when a very high reading of the thermometer had just before been obtained. He never got a high temperature with a non-registering thermometer, when he himself held the instrument in the axilla, keeping his hand pressed against the patient's arm. It is certainly difficult to avoid the conclusion that, in this case, some deception was practised, although its nature was never discovered. The girl died of disease of the lungs on March 22nd, 1880. Can a patient without being observed, squeeze or rub the bulb of a thermometer, so as to drive the mercury up?

In these cases of abnormally high temperatures the pulse and respiration did not rise in any like proportion, there was no delirium or febrile condition of the urine, and the patient did not die.

Theory of fever.—In studying the nature of pyrexia, we may, in the first place, safely assume that the sources of febrile heat do not differ in kind from those which normally keep the human body at a temperature above that of the external air: that is to say, that they are chemical and depend on oxydation of the food which is consumed. Is this production of heat increased in pyrexia?

In 1863, the late Prof. Traube propounded the theory that the amount of heat generated during fever is the same as in health, so that pyrexia would consist in a diminution in the amount of heat given off from the body. His theory has since been shown to be incorrect, but it formed the starting-point of numerous observations and experiments, by which our knowledge has been greatly increased.

In pyrexia, when the temperature has risen to a certain point, it is often stationary there for some hours; and for several days it may oscillate upwards and downwards, always remaining above normal; exactly as in health it oscillates above and below 98·4°. So that in fever, as in health, the regulation of temperature still goes on, although the point at which the thermometer stands is different. Liebermeister, in 1864, took advantage of an attack of tonsillitis in his own person to demonstrate this fact very clearly. His temperature having risen to between 102° and 103°, he exposed his body to cold air, and washed himself with cold water; and he found that this caused a slight rise of the axillary temperature from contraction of the superficial vessels and diminution of loss of heat from the skin, exactly as would have occurred under normal circumstances. The same observer, in 1868, by noting the changes in the temperature of the water of a cold bath, in which he placed a man suffering from acute pneu-

monia, was able to calculate that the immersion caused a greatly increased production of heat, far more heat being given off than would have corresponded with the mere lowering of the temperature of the patient.* So also, as Cohnheim remarks, one may throw a fever patient into the most profuse perspiration by the subcutaneous injection of pilocarpine, when the loss of heat from the cutaneous surface must necessarily be enormously increased, and yet no fall in his temperature follows.

Dr Burdon Sanderson in his lectures on fever in 1876 gave abundant evidence that pyrexia does not depend on diminished dissipation of heat (which may sometimes be increased), but on disorder of the thermotaxic mechanism.

The heat of fever, like that of warm-blooded animals in health, depends ultimately on oxidation (and other subordinate chemical processes) which takes place chiefly in the muscles and next in the liver and secreting glands, but to some extent in all living tissues. The dissipation of this heat takes place only to a small extent by conduction and radiation, but chiefly by evaporation, and this partly from the lungs, but chiefly from the surface of the body. The regulation of thermolysis, or loss of heat, is accomplished partly by the nervous mechanism of respiration, but chiefly by the vaso-motor and vaso-dilator nerves diminishing the amount of blood which circulates in the liver and hot internal organs on the one hand, and increasing the flow through the comparatively cool integuments on the other. In fever it is now ascertained that more, not less, heat is often given off than in health; but the essential point is that more heat is also produced than in a healthy person, taking so little food as a febrile patient does. The regulation of both thermogenic and thermolytic processes is thrown out of gear. The thermogenesis is increased beyond the power of the thermolysis to cope with. The nervous mechanism of the latter process is known: that of the former is more obscure, but there is reason to believe that both catabolic and anabolic nerves exist, to increase and to check the thermogenesis of the muscles. This part of the theory of fever was ably discussed by Dr Donald MacAlister in the Gulstonian lectures for 1887.

Physiologists, experimental pathologists, and clinical observers are agreed as to the existence of thermotaxic and thermolytic centres; and some progress has been made in determining their exact seat. The motor area of the cortex near the fissure of Rolando, the corpus striatum, the grey matter of the cord, and particularly the mesencephalon, are the parts which experiment and pathological observation indicate.

Dr H. C. Wood, of Philadelphia, by experimental researches on the subject made important additions to the previous evidence on this point.

Dr Hale White published in the 'Guy's Hosp. Reports' for 1884 (vol. xliv, p. 49) an interesting essay illustrating the theory of one or more "heat centres" in the brain and cord by a series of clinical cases, some of increased, others of subnormal temperature.†

A striking illustration of the fact that the physiological process of heat-regulation is still in action during the course of pyrexia, is afforded by the

* The accuracy of this calculation has since been disputed by Winternitz. "Der Einfluss v. Wärmeentziehungen auf die Wärmeproduction," 'Med. Jahrb. Wien,' 1872; and 'Virch. Arch.,' Bd. lvi, S. 181.

† See also Riegel's original paper, "Über den Einfluss des Centralnerven-systems auf die thierische Wärme" ('Pflüger's Archiv,' 1872), and Dr. Isaac Ott's recent review in the 'Proceedings of the American Neurological Association' for 1887.

persistence of the regular daily fluctuations of temperature. Wunderlich, indeed, formerly thought that the range of these fluctuations was wider than in health, even when the fever was such as would be commonly called continuous; but Jurgensen and others seem to have shown that they are identical with the normal fluctuations in every respect except that they take place at a higher thermometric level. In pyrexia, as in health, the rule is for the temperature to rise more or less constantly during the day, and to fall during the night. The minimum occurs at about 6 or 7 a.m., the maximum at about 6 p.m. The range of fluctuation appears to be generally as much as 1° C., or even a little more, so that it approaches 2° Fahr.

According to Liebermeister, these daily curves of temperature are probably due to the influence of muscular exertion and of food upon the body, notwithstanding certain obvious objections to such an interpretation of them. One of the objections is that healthy men work and eat to a much later hour in the day than 6 o'clock, p.m., after which the temperature begins to fall; this Liebermeister meets by what is termed the "principle of compensation," according to which every rise in temperature tends to be followed after an interval by a fall below the normal point; he supposes, in fact, that the power of food and of exertion to raise the bodily heat is exhausted during the early part of the day, after which the inevitable recoil takes place in spite of them. The other objection is that the daily fluctuations do not disappear when a person remains in bed all day, and takes no food. Liebermeister accounts for this by appealing to the influence of habit. Evidently the persistence of the fluctuations during pyrexia, when the patient is perhaps absolutely helpless and has fluid nourishment at regular intervals through the twenty-four hours, requires and admits of the same explanation.*

Clinical conditions of pyrexia.—The chief conditions under which pyrexia occurs, fall naturally into two groups: sometimes it is "symptomatic" or secondary to a local inflammation, sometimes it is "idiopathic" and "essential," and depends on the entrance of a contagion into the blood. It has been experimentally shown that the division of the nerves of the limb of an animal is without effect in preventing the development of fever as the result of local inflammation. The inference seems to be inevitable that inflammatory fever is caused by the entrance of a morbid agent into the blood from the inflamed tissues, and this entirely accords with the observations of Billroth and Otto Weber, who, so far back as 1864, showed that pyrexia could be produced by injecting into the blood either fresh pus or decomposing substances of various kinds.

Secondary pyrexia, however, does not always depend on inflammation.

* "The view that pyrexia is only a modification of a physiological process accords well with a doctrine which is gaining ground, namely, that this morbid condition fulfils a useful purpose in disease. The conception of fever as having a salutary influence is, indeed, as old as Hippocrates, and it can be traced all through the Middle Ages, and down to our own time; but our immediate predecessors recoiled from explanations teleological. It is only since the contagious principles of some at least of the specific diseases have been shown to be living organisms, that it has been possible to understand how pyrexia may bring about its own cure, by destroying the very agents which set it up."—C. H. F.

We must, however, remember that some microbes flourish best at a temperature above that of the blood in health, and only some of them are destroyed by a temperature equal to "high fever." Moreover, as Dr Andrew observes, although the hyperpyrexia of rheumatism appears to remove, at least for a time, other symptoms of the fever, yet a high temperature is of no good omen in practical experience when it accompanies enteric fever, scarlatina, or pneumonia.

If there be centres for heat-regulation in the cord, nothing is more likely than that cerebral hæmorrhage or the status epilepticus should cause, what we find clinically, symptomatic pyrexia without inflammation. On the other hand, there is sometimes an absence of pyrexia as an accompaniment of intense inflammations (especially of the meninges and of the peritoneum) which can hardly be accounted for except on the supposition that some counter-influence is exerted upon these thermotaxic centres, either directly or through nervous channels.

The irregular fever of idiopathic anæmia, of leuchæmia, and of Hodgkin's disease has not yet received a satisfactory explanation. That which accompanies the various forms of acute tuberculous affections probably depends upon rapid multiplication of the characteristic bacilli, or in some cases on extensive concomitant inflammation.

There are certain rare cases of pyrexia which agree in having no local inflammation as a cause, and in not being specific and contagious, which run an irregular course and are not accompanied by disturbance of the pulse, appetite, and other functions commensurate with the temperature shown by the thermometer. These cases are more common in women than in men, and in young adults than in others; and are sometimes connected with neurotic symptoms, anxiety and depression of mind, or actual hysteria. They appear to be of favourable prognosis even when the temperature reaches 104° Fahr. or higher, and may conveniently be styled *febris nervosa*.

According to Liebermeister's definition of fever, the mere fact that the temperature of the body is raised is not of itself a proof that fever is present. In tetanus the temperature is sometimes exceedingly high; but Dr Parkes, in his Croonian Lectures for 1871, suggested that the heat of the body in that disease might perhaps have a different origin from that of the specific and symptomatic fevers. A similar opinion was held by Cohnheim, who would also exclude from pyrexia the phenomena of sun-stroke. In each case it is probable that what occurs is not a shifting upwards of the point to which heat-regulation is adjusted, but a generation of heat in excess of that with which the ordinary mechanism of heat-regulation is able to deal. The same view may perhaps be taken of hyperpyrexia in general, the evidence being that the temperature neither remains stationary at a very high point, nor continues to oscillate backwards and forwards, but either goes on rising until death occurs, or falls again to a moderate level.

We may then, provisionally, arrange the conditions under which we meet with raised temperature in practice somewhat as follows:

1. Irritative inflammatory fever, probably due to poisoning of the regulating nervous centres by "ptomaines," or other soluble chemical principles derived from an inflamed part. The pyrexia is moderate when the skin or mucous membranes are affected; moderate or sometimes absent in idiopathic or "simple" inflammation of the serous membranes, and in even acute inflammations of certain viscera, as the liver and the kidneys; but always present and usually high in inflammation of the lungs and in acute tonsillitis; absent in chronic inflammations; often much increased by pain, as in cases of acute synovitis, of iritis, of syphilitic periostitis, of orchitis and inflammation of the ovary.

2. Suppurative or septic inflammatory fever. This is much higher and more constant than when the inflammation of which it is the symptom is non-purulent. It is most marked when pus is closely confined and subsides

on its liberation; but is rarely absent with purulent inflammation, whether of the connective tissues or bones, the brain, liver, and kidneys, or the serous and synovial membranes. It may be regarded as partly due to the same causes as the "irritative" form, partly to septic absorption, and that probably of microbes, as well as of toxines.

3. Pyæmic fever, where there is superadded to the pyrexia of suppurative inflammation that due to intense septicæmia with embolism.

4. Specific primary or idiopathic fever, produced by the swarms of special microphytes (or their secretions) affecting the heat-regulating centres. With these cases we must range by analogy fevers like typhus and ague, in which no microphytes have been certainly discovered, and also perhaps rheumatic fever.

5. The irregular fever of the most severe forms of anæmia—Addison's idiopathic or "pernicious" variety, Virchow's leuchæmic or splenic, and Hodgkin's lymphatic anæmic.

6. Those febrile conditions which appear to be primarily nervous in pathology, including *tetanus*, *heat-stroke*, and any genuine cases of *paradoxical temperature*.

7. Lastly, the cases of continued pyrexia above described which may provisionally be grouped together as *febris nervosa*.

Course of pyrexia.—In the *initial stage* of fever, there is no question that the loss of heat from the cutaneous surface is greatly diminished. As there is no reason for supposing that the evaporation from the lungs undergoes a proportionate increase, we are probably justified in assuming that the total loss of heat is much less than under ordinary circumstances. We have seen that, as De Haen long ago pointed out, the temperature of the deeper parts of the body during a rigor is actually higher than normal, and in fact rises rapidly. Now, since the introduction of the thermometer into clinical practice, this has commonly been taken as proof of the false conclusion that the painful feeling of coldness of the limbs, and of the skin generally, is merely a "subjective sensation produced by the state of the peripheral nerves." The truth is that the low temperature of the surface is just as much a physical fact as the high temperature of the blood in internal organs. One has only to feel the shrunken hand of a man in the cold stage of ague to be satisfied that he is under no illusion when he complains of being cold, and a surface thermometer affords precisely the same indication by the slowness with which it rises above the temperature of the surrounding air, and the comparatively low point which it reaches, however much time may be given to it. Thus Schülein, among certain observations of surface temperatures (to be presently cited), gives a case of tertian ague; and in his chart it is most striking to notice, how, during each attack, at the precise moment when the temperature in the axilla was rising from 98° to 104° or 105° F., that between the toes fell still more sharply, from 95° to 86°, or even below 77°. The cause of the chilliness experienced by such a patient is that the peripheral arteries are contracted and do not allow of the passage of a sufficient quantity of blood to warm the superficial tissues, and to compensate for the loss which is always going on by radiation and conduction, to whatever extent the exhalation of fluid from the skin may be diminished. A necessary consequence is a great fall in the temperature of the skin, and one must not forget that this in turn involves a lowering of the amount of heat-loss, which affords one of the means by which the rapid rise of tempera-

ture during rigor is brought about. It has, however, been calculated by Zimmermann and by Liebermeister that there is, besides, a very great increase of heat-production during this stage.

During the *fastigium* the temperature of the body may remain stationary, or at any rate undergoes comparatively gentle oscillations, so that for its maintenance no such antagonism between heat-production and heat-loss is required as for the rapid rise in the initial period. However, in many instances there is still a marked distinction between the temperature of the skin and that of the deeper structures. These cases afford special proof of the importance of the clinical thermometer, inasmuch as the axillary or the rectal temperature is found to be above normal while the patient's skin feels cool to one's hand and he has no sensation of feverishness. But the comparatively low temperature of the surface is a reality; and since the heat-loss by conduction and radiation is certainly less than when the skin is hot, it is fair to conclude that for the same degree of internal temperature the production of heat must also be less. On the other hand, there are certain diseases in which, when one places one's hand upon the patient's skin, one feels it to be pungent and burning in a very remarkable degree. Addison used to teach that in acute pneumonia the skin possessed a heat which was not observed in any other disease except perhaps scarlet fever. When the thermometer was introduced into practice his dictum seemed to have no physical foundation. An attempt was made to explain away the difficulty by saying that the surface was peculiarly dry in acute pneumonia; but this obviously was beside the question, since at any temperature above that of one's own hand a moist skin must undoubtedly feel hotter than a dry one, if it were possible to prevent the temperature from being lowered by the evaporation which inevitably occurs. The true solution of the difficulty is that in acute pneumonia the temperature of the surface is maintained at a point which is very nearly as high as that of the deeper parts, instead of being far below it, as in most other diseases, even when there is no moisture upon the skin. This was established by Schülein, as the result of a series of careful observations published in 'Virchow's Archiv' for 1876, upon the relation between surface temperature and internal temperature in various diseases. His method was to insert a thermometer with a very small bulb between the first two toes, fastening them together by means of an elastic ring. And he found that whereas in other diseases (including enteric fever, acute rheumatism, and phthisis) the instrument in this position always indicated a much lower temperature than one placed in the axilla, there were three diseases in which the difference was very slight indeed, namely, acute pneumonia, measles, and scarlet fever. In these almost every movement of the axillary temperature upwards or downwards was accompanied by precisely the same movement of the temperature between the toes; whereas no such relation could be traced between the two sets of observations in any other febrile complaint. It must, however, be remarked that in many diseases surface temperatures are from time to time taken which are absolutely as high as those in acute pneumonia; and it is probable that a still more striking confirmation of Addison's doctrine would be obtained if we were only to note the rapidity with which a surface-thermometer rises, when applied to the skin in different complaints. For in that way we should be estimating the amount of heat which the surface is giving off by conduction; and it is this that one's hand appreciates when laid upon a patient's skin. It is almost certain that at least one other disease would have to be added to

those enumerated by Addison, namely, acute rheumatism when complicated by hyperpyrexia.

It is evident that in order to maintain such a uniform high temperature of the superficial as well as of the deeper parts, in spite of the great loss of heat which must necessarily occur, the generation of heat must be far greater in all these complaints than in others in which only the interior of the body is raised to a similar degree of heat. So, also, when the skin perspires freely during the *fastigium*, the temperature within remaining high, there can be no doubt that the production of heat must be proportionately increased.

During the stage of *defervescence* the profuse sweating which so often accompanies it, when crisis takes place, plays an important part in bringing about the rapid fall of internal temperature. But it is not to be regarded as the cause of the defervescence; the fact being that the state of pyrexia has come to an end, and that the heat-regulation is, therefore, no longer set for an abnormally high point.

Concomitants of pyrexia: tissue-change and wasting.—The sources of febrile heat are, as above stated, identical with those which maintain the normal temperature of the body. Science has now advanced beyond the point at which Virchow stood when, in 1854, he declared that the elevation of temperature in pyrexia "must arise from an increased tissue-change." Liebermeister and other observers have indeed shown that the amount of urea excreted in the urine during fever surpasses by at least 70 per cent. that which is voided by a healthy person living on the same diet. Careful observations by Ringer in a case of ague established the fact of the same excess of excretion of urea for intermittent pyrexia. But it is now well known that the production of heat may be largely dependent upon the increased oxidation of various substances, such as sugar, which have never formed part of the substance of the body. Both Leyden and Liebermeister have proved that the excretion of carbonic acid gas also is excessive in fever, the increase amounting probably to at least 50 per cent. It is essential to bear in mind, however, that neither the quantity of urea, nor that of carbonic acid, is nearly so great as that which may be discharged without any rise of temperature by a person who is taking active exercise, or even by one who has eaten a large meal of animal food with much fat. Thus we are brought back again to the same point as before, namely, that pyrexia cannot be due to any special rate of heat-production, but must depend upon an alteration in the point for which heat-regulation is set.

There is, however, no more striking feature of pyrexia than the wasting of the body which accompanies it; and this often seems to go on quite as rapidly as one could have expected, even if Virchow's dictum had been true in the strictest sense. Formerly there was a tendency to pay too little attention to fever as being, in itself, a cause of loss of weight, and to ascribe this result rather to a drain of pus, or of any other discharges which might occur in a particular case. It may therefore be worth while to cite a case of Liebermeister's in which a patient who had an abscess discharging about three ounces of pus daily, lost from fifteen to twenty pounds in weight during two months, while his temperature was at 101° or 102°, but regained it afterwards when he had no fever, notwithstanding that the suppuration still went on as before. No doubt an inability to digest food plays an important part in bringing about the wasting; it is well known that the secretion of milk ceases during pyrexia, and one may fairly assume that there is a similar

interruption in the formation of saliva (to which, in part, the dryness of the mouth is due), and also of the gastric and intestinal juices. That it is not merely a question of loss of appetite appears probable from an observation of Niemeyer's, who, comparing together a healthy man and one suffering from fever during a period of two days in which they lived on exactly the same food, found that the latter lost much more weight than the former. Liebermeister remarks that the wasting is sometimes concealed by the presence of an excessive amount of water in the tissues: he has observed that from this cause the weight of the body may be raised by as much as ten pounds, although there may be only a very slight œdema of the ankles to indicate the presence of such an abnormal condition. He believes that persons who are in good health and well nourished invariably lose flesh when they become the subjects of pyrexia; but he admits that those who are already wasted may undergo no further emaciation, and may even gain weight in spite of the supervention of a febrile illness. According to a calculation made by Leyden, the daily loss of substance in fever amounts on an average to 7 parts per 1000 of the whole body-weight. Cohnheim has pointed out that, if this be correct, it should take only about eight weeks of a tolerably severe fever to kill a fairly nourished man by the mere destruction of his tissues; at least, if one may appeal to the observations of Chossat, which showed that to the higher animals a loss of 40 per cent. of their weight is directly fatal.

The blood doubtless wastes simultaneously with the solid structures, and Parkes and others have supposed that the excess of pigment in the urine depends upon an undue disintegration of red discs. Hæmometric observations, however, by Baxter and Willcocks, lead to the conclusion that, with a single exception, febrile diseases cause no diminution in the proportion, either of discs or of hæmoglobin, in a given amount of blood. The exception is ague, in which, according to Kelsch, there is a great decrease of corpuscles. In other febrile states the whole volume of the blood is lowered, while the relation of its fluid and solid constituents remains normal.

Increased rapidity of pulse.—We have seen that it is only of late years that elevation of temperature has been recognised as the characteristic and essential feature of pyrexia. Previously, acceleration of the pulse, rapidity of breathing, diminution of the secretions, and a variety of other phenomena, were supposed to be not less important indications of it. Now, it is a matter of some consequence to determine whether these several symptoms are directly dependent upon the increased heat of the body, or whether they must be regarded as independent effects of the various causes of fever. In the opinion of the best modern writers, the rapid pulse which generally accompanies pyrexia is a result of the heightened temperature; Cohnheim adduces in support of this view the well-known fact that the frog's heart beats more quickly in proportion to the warmth of the surrounding air. Liebermeister insists on the effect which hot and cold baths respectively have, when they raise or lower the temperature of the body, of simultaneously accelerating or slackening the pulse. He even lays down as the rule, based upon a considerable number of observations (which, however, vary widely among themselves), that for each degree centigrade above the normal temperature there should be a rise of the pulse by eight beats above the standard rate of eighty. It is admitted, of course, that various other

circumstances may affect the pulse-rate of febrile patients, as of healthy persons, or of those suffering from other diseases. Cohnheim insists on the effect which stimulation of the vagi may have in slowing it, and cites the fact that in basilar meningitis the pulse is often infrequent in spite of high fever; but neither he nor Liebermeister seem to have looked out for those negative instances by which their theory could best be brought to the test, namely, the exceptional cases in which a severe inflammatory process, or some other condition that usually gives rise to pyrexia, happens to run its course without elevation of temperature. Such instances are sometimes met with in peritonitis, in diphtheria, and in meningitis; and then the pulse is often, though not always, quickened. Does not this cast some doubt on the pulse-rate being dependent on the pyrexia?

It is important to observe that the rapidity with which the blood flows in pyrexia, and the arterial *blood-tension*, are by no means proportioned to the acceleration of the heart's action. At the commencement of fever, when the pulse feels full and hard, it is probable that the circulation is often really more active than in health. Much stress was formerly laid upon the "*sthenic*" character of such cases. In the 'Med. Times and Gaz.' for 1873, Dr Mahomed has given sphygmographic tracings of the pulse in various forms of fever, showing that this term is not without meaning; for in certain cases the vessels are full, the arterial tension is high, and the pulse bears considerable pressure. It is therefore a mistake to say that a febrile pulse is necessarily dicrotic. On the other hand, when pyrexia has lasted for any length of time, it almost always assumes an "*asthenic*" type, and in many instances this is the case from the very first. It would then seem that the circulation is more sluggish than natural, one proof of this being that the blood tends to stagnate in the more dependent parts of the body, so that what are termed hypostatic congestions arise in the lower lobes of the lungs, and beneath the integument of the back and buttocks, and in the dependent part of the legs as the patient lies in bed. The pulse still remains quick, but it is now soft, feeble, and often small. The sphygmograph shows a highly characteristic condition of arterial relaxation, with low pressure; dicrotism becomes a prominent feature; and in many cases the pulse is even hyperdicrotic. In fact at this stage of fever the heart, although its beats follow one another so quickly, empties itself incompletely and discharges less rather than more blood into the arteries. Often, indeed, thrombi form in those parts of the heart's chambers which are farthest from the orifices.

Until recently, the impairment of the cardiac beats was held to be sufficiently explained by the fact that its muscle, like all the other tissues, becomes badly nourished as pyrexia goes on. Of late, however, some observers have thought that the cause of the enfeeblement of the heart's action in pyrexia is not merely its wasted condition, but the occurrence of definite morbid changes in its texture. We shall find that in cases of enteric fever an affection, known as "parenchymatous degeneration" or "cloudy swelling," is found in the liver, in the kidneys, in the heart, in the voluntary muscles, and elsewhere. This, however, is by no means peculiar to any one febrile disease, and Liebermeister and others have maintained that it is the direct result of elevation of the body heat, reaching a certain degree of intensity, and protracted over a somewhat long period of time. This view is supported by the experiments of Dr Wickham Legg, who found ('Path. Trans.,' vol. xxiv) that the liver, the heart, and kidneys were

granular in animals killed by the action of heat, even when its duration was only for a few hours. On the other hand, Cohnheim maintains that, although guinea-pigs kept for several days in a high temperature exhibit a fatty change in their tissues, there is nothing really resembling "cloudy swelling." He insists on the absence of such an appearance in acute pleuro-pneumonia, and its occasional presence when there has been no fever (as in carbonic oxide poisoning) as proofs that Liebermeister's opinion is erroneous. He even declares that the statements as to the frequency of degenerative changes in febrile diseases are overdrawn, and that in a large majority of the bodies of those who have had intense pyrexia, fatty gland-cells and muscle-fibres are not at all more common than they would have been if death had taken place in a different way. The question is one of great importance, and bears upon the supposed causes of cardiac dilatation and of permanent failure of the muscular substance of the heart.

Other febrile symptoms.—The increased frequency of the *breathing* in pyrexia is also attributed to the action of heated blood upon the respiratory centre; and this view is supported by a very interesting experiment, performed by Goldstein in Fick's laboratory, of warming the carotid blood alone; he found that the respiration was thereby accelerated. Cohnheim adduces in illustration of this theory, the fact that in acute pneumonia the breathing ceases to be rapid after the crisis of the fever, notwithstanding that the affected part of the lung still remains hepatized. Apart from pyrexia there is, however, no doubt of the close dependence of the regulating centre of respiration on that of the heart.

Cohnheim is indisposed to admit that the *cerebral symptoms* which attend so many cases of fever are dependent solely upon the increased temperature of the blood, and of the substance of the brain. He points out that in relapsing fever the thermometer rises to a great height with but little disturbance of the sensorium, and that in febrile diseases generally no relation can be traced between the intensity of the fever and the severity of the delirium or stupor. He does not even allow that the question is settled by the marked effect of a cold bath in restoring the mental faculties of a patient suffering from fever; for, he observes, it may be a consequence rather of the improvement of circulation which results from the bath.

Obscure in some points as is the connection of these disturbances of other functions with pyrexia, there is no doubt of their practical importance at the bedside; and it may be well briefly to enumerate them before leaving the subject.

In addition then to the raised temperature which is the constant and governing phenomenon of fever, we observe to a greater or less extent, according to the severity and duration of the pyrexial state: (1) Acceleration of the pulse and respiration; (2) thirst; (3) disturbance of secretion, and probably as results, (4) loss of appetite, a dry and furred state of the tongue and constipation; (5) scanty and high coloured urine rich in urea, often albuminous, and depositing lithates; (6) pains, particularly headache, not specially frontal, vertical, or occipital, but central and deep seated; and also muscular pains in the loins, back, and limbs; (7) delirium; (8) emaciation.

The *treatment* of pyrexia by baths and antipyretic remedies will be most usefully discussed in the sections on enteric fever and acute rheumatism, which offer the most frequent and urgent occasions for their use.

Subnormal temperature.—It is an interesting question whether the tempe-

rature of the body ever undergoes a change in the direction opposite to pyrexia, the heat-regulation centre being set at a point below the normal instead of above it. We shall hereafter find many instances in which a thermometer placed in the axilla remains unduly low, but probably in these cases the internal organs generally maintain a temperature nearly as high as ever, at least until death is obviously impending. Cohnheim says that this is the case with those who suffer from inanition as the result of stricture of the œsophagus, of starvation from other causes, or of extreme anæmia. Even were it not so, we should still have to show that an alteration in the heat-regulation had occurred, and that the failure to maintain the normal temperature was not a result of an insufficient production of heat. Such a lowering of temperature by "*force majeure*," as Liebermeister terms it, is well seen in persons who are picked up insensible in the streets during cold weather. Cohnheim alludes to cases of this kind, in which the thermometer in the rectum has not risen above 86°, 79°, or even 75° F. The pupils are then dilated and sluggish, while the pulse and the respiration are greatly reduced in frequency; but unless things have gone too far for recovery to take place, such patients under suitable treatment regain their normal temperature within a few hours, and sometimes pass into a condition of reactive pyrexia.

The two conditions, in which (apart from inanition and from the reaction after pyrexia) the temperature is most frequently found subnormal, are diabetes and the stage of collapse in cholera. It is also habitually subnormal in the curious affection described by Sir William Gull as a cretinoid condition in adults, and since named myxœdema. The lowest temperatures, however, have been observed in certain cases of injury to the cord: in one recorded by Mr Hutchinson the temperature in the rectum was not above 80·6° F.

INFLAMMATION

Notæ vero inflammationis sunt quatuor: rubor et tumor, cum calore et dolore.
CELSUS.

Historical review: Virchow: William Addison, Waller and Cohnheim: Goodsir—Direct observation of inflammation in animals—Redness, swelling, pain, heat, pyrexia—Exudation: membranous, catarrhal, purulent, diphtheritic, gangrenous inflammation—Repair—Causes of inflammation: irritants and predisposition—Chronic inflammation—Granuloma.

No one, at whatever period of the world's history, could have applied himself to the study of disease, without seeing that the hot, painful, reddened state of the eye which follows the entrance of a particle of dust within the lids, is typical of a morbid change that is of frequent occurrence in every part of the body accessible to observation. Hence it is not at all surprising that before the end of the second century we find, in the writings of Galen, inflammation (φλεγμονή) already characterised by its four cardinal symptoms: heat, redness, swelling, and pain. To use the words of the late Prof. Hughes Bennett, inflammation has been in all ages "the pivot upon which medical philosophy has revolved." But, for that very reason, there is little use in our now attempting to recapitulate the different views and theories with regard to it which have been proposed. It is scarcely too much to say that only the most recent advances of pathology and histology have rendered possible a real understanding of inflammation.

Very soon after the promulgation of Schwann's doctrine, in 1839, that nucleated cells constitute a principal element of animal structures, pathologists discovered the presence of these bodies in inflamed parts; but at first it was supposed that they developed themselves in the interstices of the tissues by molecular aggregation, in accordance with the revived opinion that this was a common mode of origin for cells in general. Virchow, however, in his masterly lectures on 'Cellular Pathology,' published in 1858, laid down as a dogma, *omnis cellula e cellulâ*. Upon this foundation he erected a complete theoretical system, assuming that the cells of the connective tissues throughout the body undergo multiplication or "proliferation," so as to generate the "exudation-cells" or "pus-cells" of inflammation.

Even before Virchow's views were made known, certain observations had already been recorded in this country, which, although they at first attracted little notice, nevertheless involved conceptions as to the real nature of cells that have since proved to be more accurate than his. But the first shock to the system which Virchow had elaborated was given by one of his pupils, Recklinghausen. He showed, in 1863, that pus-cells, instead of being rounded bladders, each with its cell wall and its nucleus, are during life solid masses of gelatinous substance, which are constantly changing their form,—now throwing out delicate processes, and now drawing them in again,—and that they actually possess the power of moving from place to place. Four years

later, in 1867, Cohnheim, who also was a pupil of Virchow, discovered that in the mesentery of the frog, when it becomes inflamed under exposure to the air, the white corpuscles of the blood can, with the aid of the microscope, be distinctly seen to make their way through the walls of the smaller vessels, so as to become pus-cells. This very fact, however, had been demonstrated as far back as 1846 by the late Dr Augustus Waller, then in practice at Kensington. His investigations were made on the tongue of the frog. Still earlier, in 1843, Dr William Addison, of Great Malvern, had insisted on the transformation of the colourless corpuscles of the blood into pus-cells, and described the former not only as "lining the vessels" in the web of the frog when inflamed, but also as "lying among the fibres forming their walls and exterior to their boundary." The resuscitation and general acceptance of views which for so long a time were neglected should make us cautious in rejecting any statements that are based upon direct observation, however much they may clash with our preconceived opinions.

In those countries in which Cohnheim's experiment is not forbidden by law, it is performed in the following manner:—A male frog, which has been rendered quiet by curare, has an incision made into the abdominal cavity, large enough to allow a loop of intestine to be drawn out, with its mesentery. It is then placed upon its back on a broad glass plate, which has been fitted with a thin glass disc for the convenient reception of the mesentery, and with a semicircle of cork to which the intestine is to be pinned. Under the microscope, the circulation can now be seen to go on naturally. But the contact of air appears to act as an irritant, and inflammation soon sets in. In from fifteen to twenty minutes the arteries are observed slowly to dilate, until at the end of an hour or two their diameter is nearly twice as great as before. A little later a similar change begins in the veins. At first the blood-stream perhaps flows more quickly than before, but very soon its rapidity begins to diminish, so that the oval red blood-discs can be distinctly seen in the arteries, at least during diastole. A striking change is now noticeable in the veins. Leucocytes begin to fall out of the middle of the current, and loiter against the sides of the vessel, rolling over and over, and sticking from time to time, when their soft substance yields to the pressure of the fluid upon them so that they become pear-shaped. Before long the channel of the veins becomes lined by a thick layer of these bodies, which lie at rest, while the central current of red discs goes on as before. In the capillaries, too, the leucocytes are arrested here and there; but between them there are seen many red discs also adhering to the walls. The most wonderful thing of all is that outside the contour of these vessels there gradually appear a number of minute rounded bodies, each of which is connected with a leucocyte within. Thus the leucocytes may be said to have assumed a dumb-bell form. By an imperceptible process, the extra-vascular part keeps growing bigger, and the intra-vascular part smaller, until at length the latter altogether disappears; whereupon the leucocyte resumes a more or less globular shape, and now lies close to the vein, but outside it. The result is, that large numbers of leucocytes are soon collected not only in the immediate neighbourhood of the vessels, but in all the interstices of the surrounding tissues. At the same time a quantity of fluid exudes, which reaches the free surface of the mesentery and coagulates there, forming a membranous layer, itself thickly set with leucocytes.*

* The important fact of the white corpuscles adhering to the sides of the vessels in the web of the frog's foot had been observed and figured by Dr C. J. B. Williams, in his 'Prin-

The separation of the leucocytes from the red discs flowing through the mid-channel of the veins, and their collecting against the walls of these vessels, are direct physical results of the slowing of the blood-current. The process of *emigration* must be referred to the power of spontaneous locomotion possessed by the leucocytes themselves. It seems, however, to depend to a certain extent upon their being under pressure from the blood, for Cohnheim has observed that it instantly ceases when the flow of blood through the main artery of the part is arrested. But, on the other hand, it is not due solely to blood-pressure, for this is actually less than under normal conditions where no emigration seems to go on, at least in the case of tissues which are not in an embryonic state.

Professor Julius Arnold and Mr Purves have maintained that the points at which leucocytes emerge from the vessels are always situated in the meeting lines between the endothelial cells. But Cohnheim argues that at any rate actual orifices or stomata can hardly be present, or they would give exit also to an unaltered liquor sanguinis, whereas the fluid which exudes during inflammation is of different chemical composition, and contains less solid matter in solution.

Before the time of Virchow, a favourite topic of speculation had been whether parts into which no vessels penetrate could be said to undergo inflammation. One of the merits of his system was that it placed the question on its right footing by showing that the distinction between vascular and non-vascular tissues was after all only one of degree, and that a minute islet of liver-substance ought to be regarded as being outside the blood-current, no less than the cornea or the cartilage of a joint. Nor did Cohnheim's investigations modify this conclusion, but rather carried it a step further; for he actually proved that leucocytes could penetrate into the interior of the cornea from the blood. It had been shown by Von Recklinghausen that when finely divided vermilion was injected into a lymph-cavity in the frog, the leucocytes would take this substance into their interior, or "feed" upon it; and Cohnheim found that after injecting pigment into one of the aortæ many of the leucocytes which appeared in the cornea under inflammation were coloured, so that they had evidently been derived from the circulatory fluid. Still, however, it could be maintained that others of them were formed by proliferation. This view was, and is still, vigorously upheld by Stricker, who described the fixed corpuscles of the corneal tissue as breaking up into amœboid masses, containing bodies which he believed to be the germs of future pus-cells. Other observers afterwards pointed out that by more refined histological methods the stellate corpuscles could be seen in a cornea which was already full of leucocytes; and although it seems to be a fact that their nuclei do undergo division, this is probably an indication (as Dr Thin has suggested) of commencing disintegration rather than of germination. The observations which Cohnheim, writing in 1877, deemed most worthy of notice, as running counter to his own, were some which had been made by Böttcher. He cauterised the minutest possible spot in the centre of the frog's cornea, and showed that pus-cells were to be found in the neighbour-

ciples of Medicine' (1843). Mr Wharton Jones had detected the same phenomena and accurately described the dilatation of the vessels and stasis of the blood ('Guy's Hospital Reports,' New Series, vol. vii, 1850), and Mr (now Sir Joseph) Lister had confirmed and extended these observations by his own (also carried out on the web of the frog's foot) in the 'Philosophical Transactions' for 1858. One of the important points established by Lister was that the dilatation of the arteries depends on paralysis of the vaso-motor nerves.

hood of the injured part, whereas there was no marginal opacity such as would have indicated that they had come from the conjunctival vessels. Cohnheim's rejoinder was that they might have been derived from the fluid secretion which covers the free surface of the eyeball. This, which at first seemed to me a very far-fetched solution of the difficulty, appears to have been since established by the experiment of placing a dead cornea, in which a puncture has been made, into a healthy conjunctival sac for a few hours; "it remains transparent," says Dr Sanderson in his Lumleian Lectures for 1882, "everywhere excepting in the neighbourhood of the injury," so that a breach of surface is evidently all that is necessary to enable leucocytes from the conjunctival fluid to make their way into corneal tissue. It has also been shown that a limited part of the cornea may be destroyed without any opacity of the adjacent tissue resulting, if the caustic employed be chloride of zinc, which does not disintegrate the protective epithelial covering.

It seems impossible to obtain an adequate conception of inflammation, without taking into account its relation to the physiological process of repair. When a part is at all severely injured, the removal of damaged tissue-elements is an essential preliminary to the work of reconstruction. May not the emigration of leucocytes in inflammation serve this especial purpose of clearing away such portions of an injured structure as are no longer fit to remain? We have seen that leucocytes are capable of taking up granules of vermilion; and it is well known that they also "feed" upon milk globules when placed in their way. May we not assume that they can also remove damaged cells or fibres? This very doctrine was promulgated, forty-five years ago, by the late Prof. Goodsir. In his 'Anatomical and Pathological Observations' (1845) speaking of "a rapidly extending ulcerated surface," he described "a peculiarly endowed cellular layer, which takes up progressively the place of the subjacent textures;" and a little further on he attributes the separation of a dead portion of bone to the "cells of the newly-formed cellular mass, contained in the Haversian canals . . . . taking it up as nourishment, and substituting themselves in its stead."* The same explanation is obviously applicable to the detachment of a slough in the softer tissues, and perhaps even to the formation of an abscess-cavity, and to the thinning of the roof of an abscess which is about to "point." We may also have recourse to it when we find that, in certain parts of a solid organ, a dense infiltration of leucocytes is attended with disappearance of the normal structure, although there is no obvious gap or breach of continuity; this, for example, may often be observed round the Malpighian capsules of the kidney, when it is in a state of inflammation.

Such an hypothesis seems more satisfactory than the view of Cohnheim, who appears to place the inflammatory process on a merely physical basis; ascribing it to a molecular change in the walls of the blood-vessels, wrought directly by the irritant which sets up the inflammation. In support of this view he cites the experiments of Winiwarter, who found that the vessels of an inflamed part allowed a solution of gelatin to transude through them under a lower pressure than under normal conditions. But probably the change in question is only a part of the general softening of all the tissues, which has long been known to constitute one of the phenomena of inflamma-

* See pp. 404, 406 of the second volume of Goodsir's Memoirs, republished by his successor Prof. Turner, of Edinburgh, in 1868. Also Prof. Redfern's papers on ulceration in articular cartilage, 'Edin. Monthly Journal,' Sept., 1851.

tion. An acutely inflamed bone is, as Paget remarked, so soft that a knife will easily penetrate it; the ligaments of an inflamed joint yield, allowing the bones to be displaced and distorted; and we are accustomed, in the dead-house, to regard a diminished resistance of the texture of a lung as one of the best rough tests of it having been the seat of acute pneumonia.

Before we quit the study of inflammation in cold-blooded animals, some further phenomena must be mentioned which belong to its more severe forms. When croton-oil is smeared over the tongue of a frog, the blood in the superficial capillaries passes into a condition known as *stasis*. It consists in complete arrest of the circulation, with coagulation of the blood; and it corresponds with the condition which in larger vessels is called *thrombosis;* in fact, the two are often associated. A still better way of observing severe inflammation is to apply caustic to a circumscribed spot on the tongue of the frog. This produces what may be described as a series of concentric zones. In the middle all the tissues are killed; or, in other words, an *eschar* is formed. Next comes an area of absolute stasis, in which, according to Cohnheim, the vessels alone are destroyed. Further outwards, the blood-stream is almost stagnant, and the capillaries are choked with red discs, which escape from them in large numbers. Beyond this again the emigration of leucocytes is the principal change. Last comes a zone in which the vessels are merely dilated, while the circulation though them is somewhat retarded. However, it is not clear to me that stasis has been proved always to depend upon the occurrence of alterations in the vascular walls, exceeding in intensity those in the other tissues. At any rate, no such conclusion can fairly be drawn from the well-known experiments made by Ryneck, of Gratz, in 1870. He showed that stasis could be set up by irritation in the web of a frog, after defibrinated mammalian blood, or even milk, had been substituted for the natural circulating fluid of the animal; but that, on the other hand, when a solution of chromic acid or sulphate of copper had once been passed through the blood-vessels, even for a few moments, no such effect could be produced. The same is true of a frog in which the blood is replaced by normal salt solution. But these observations, although they disprove the now obsolete doctrine that inflammation is dependent upon a change in the blood, have little bearing on the questions which are now under discussion.

In warm-blooded animals the attempt to watch the inflammatory process directly with the microscope was at first found to be attended with considerable difficulties; but these were gradually overcome. Mr Wharton Jones had observed in the bat's wing that the vessels when inflamed dilated, that the blood-stream slackened, and that the corpuscles crowded together to the sides of the vessel ('Med.-Chir. Trans.,' 1853). Mr (now Sir James) Paget, in his 'Lectures on Surgical Pathology' published in the same year, also used the bat's wing, and observed the very short period of initial contraction, the subsequent dilatation, and other phenomena as afterwards described, excepting the emigration of leucocytes. In 1870 Dr Sanderson and Professor Stricker, of Vienna, contrived an admirable method of studying the circulation in the mesentery of the guinea-pig, which was demonstrated at the meeting of the British Association in that year at Liverpool, and this method was afterwards applied to the observation of inflammation. Lastly, Professsor Thoma published in 'Virchow's Archiv' for 1878 a series of microscopical observations on inflammation in the mesentery or the omentum of dogs, cats, rabbits,

and guinea-pigs. The only difference between his results and those described above seems to be that he could not satisfy himself that the calibre of the arteries became wider. Emigration of corpuscles and exudation of coagulable fluid occur in precisely the same way as in frogs.

The phenomena of inflammation.—We may now proceed to trace out in detail such explanations of the four cardinal symptoms of inflammation as accord best with our present views.

1. *Rubor.*—The redness of inflammation depends partly upon the dilatation of the veins and other blood-vessels of the affected area,* partly upon the accumulation of blood-discs in its capillaries. If the separate vessels are visible, the redness is spoken of as "injection;" if they cannot be seen, it is said to be "diffused." The tint is somewhat purple, which seems to be due not only to the preponderance of dilated veins, but also to an augmented deoxidation of the blood in the capillaries, in consequence of the retardation of the current through them. When stasis occurs, this also causes redness; and at all but the earliest stages hæmorrhages also play an important part in the production of rubor. They often give to it a punctiform character, and they may be further distinguished by not fading beneath the pressure of the finger. On the other hand, the presence of any considerable quantity of exudation tends to conceal the red colour, even where it does not actually compress and empty the vessels: thus, at advanced periods of the morbid process, the affected tissues often become grey or even yellow. When non-vascular structures become inflamed, the redness of course shows itself in the vascular parts around, from which they derive their nutriment; for instance, in the conjunctiva at the margin of the cornea, and in the synovial membrane about articular cartilages. After death, so much of an inflammatory redness disappears as was due to fluid blood in the interior of the vessels.

2. *Tumor.*—This may, to some extent, be due to vascular turgescence, but the chief cause of it is exudation. Lassar, Cohnheim's assistant, showed some years ago that the stream which flows away through the lymphatics of an inflamed part is greatly augmented. For example, he irritated the paw of a dog, sometimes by immersing it for a short time in hot water, and sometimes by rubbing in croton-oil; and he found that the lymphatics in the limb above became greatly dilated, and that when he introduced a cannula into one of them the fluid which escaped through it was increased to several times its normal quantity. Evidently, therefore, the swelling corresponds, not with the whole amount of exudation, but with the excess of it, as compared with what is taken up again. Cohnheim even holds that inflammation may run its course, and be attended with exudation and with the emigration of leucocytes, and yet lead to no swelling, provided that re-absorption goes on at a proportionately rapid rate. He suggests, for instance, that this may be the case with the eruptions of scarlet fever, and other exanthemata, in some of which the subsequent occurrence of desquamation of the cuticle shows that there was more than a mere hyperæmia. In the case of erysipelas we shall find a striking example of the same thing.

In distributing itself through the inflamed structures, exudation follows the lines of least resistance. In connective tissue, and in the stroma of a parenchymatous organ, it fills the natural interstices. Wherever there is a

* According to Prof. Thoma, in mammals the veins only dilate, not the arteries also, as in frogs ('Virchow's Archiv,' 1878).

gap or interspace it accumulates. It covers the free surfaces of serous membranes. Mucous membranes throw it off, to mix with their natural secretions. In the skin, it penetrates through the deeper soft layers of the cuticle, and it often raises the horny layer to form small collections of fluid, which are termed vesicles and pustules.

3. *Dolor.*—The pain of inflammation is usually, and no doubt correctly, attributed to the compression of the sensory nerves by distended vessels and afterwards by exudation. Thus it often has a throbbing character, being momentarily intensified by each pulsation of the heart. It is generally accompanied by "tenderness;" or (in other words) it is increased by pressure from without. Doubtless a general relation can be traced between the amount of pain induced by inflammation in different parts and the abundance of their sensory nerves; but, on the other hand, it is well known that some tissues, such as ligaments and bones, may become exceedingly painful when inflamed, although they are not naturally very sensitive. The determining factor in such cases appears to be the degree of resistance to distension and swelling which is offered by the structure inflamed.

4. *Calor.*—That those parts which are most accessible to observation become hotter than natural when inflamed, is matter of common knowledge; anyone may satisfy himself of it by placing one hand over an acutely swollen joint or a recently formed abscess, and the other upon the corresponding spot on the opposite side of the body. But contradictory statements have been made as to the relation between the temperature of an inflamed part and that of the blood and of the deep internal organs.

In 1860 Mr Simon made a series of observations with a small thermo-electric apparatus, so shaped that it could be thrust like a pin into the soft tissues, or even into the interior of large vessels; and he found not only that the arterial blood flowing towards a severely injured limb in a dog was always less warm than the venous blood flowing away from it, but that the inflamed tissues themselves were warmer than either kind of blood. He did not attempt to measure the amounts of difference of temperature which he believed that he detected; and if (as is possible) they were very small, there may be the less difficulty in supposing that there was some source of error in his experiments. However, it appears to be certain that he was wrong in concluding that inflammation is attended with a special local production of heat. For Jacobson, of Königsberg, who afterwards investigated this question with more accurate apparatus, found ('Virchow's Arch.,' 1870) that the temperature of the skin and of the muscles down to the bone never, even under conditions of the most intense inflammation, reaches that which exists in the rectum, the vagina, or the peritoneal cavity, at the same time. The difference was generally as much as 2° or 3·5° Fahr. As for the relation between the temperature of one inflamed part and that of the opposite side of the body, the difference was always less in proportion as the distance from the surface was greater. Thus, whereas a rabbit's ear when inflamed was warmer than the other ear by 7° or 8° Fahr. the temperature of the deep muscles of a limb under the same circumstances seldom exceeded that of the same structures on the opposite side by more than 1°. It would follow that the internal organs under inflammation continue to be of a temperature approximately the same as that of the blood. Jacobson showed by direct experiment that in pleurisy the affected cavity was either of the same temperature as, or even slightly colder than, the other one. Afterwards,

in December, 1879, M. Peter brought before the Paris Academy of Medicine a series of observations made upon patients affected with chronic peritonitis, and drew from them the conclusion that there was a very considerable local production of heat independently of the general bodily temperature. But what he really showed was nothing more than that the temperature of the abdominal wall may in such cases exceed that of the axilla by as much as 3·5° Fahr. Unfortunately he omitted to place a thermometer in the rectum, and, therefore, it may be fairly contended that in his cases the temperature of the inflamed part may after all have been no higher than that of the blood.

If Jacobson's observations are correct, the real increase of temperature in the skin and other superficial structures when inflamed may yet receive a very simple explanation. For the blood-current is to be regarded as a great warming apparatus, which carries to the tissues all over the body heat that is generated chiefly in the liver and other glands, and in the muscles. If there be no additional local production of heat, the temperature of each part must be the resultant of four varying conditions: (1) the temperature of the arterial blood supplied to it; (2) the proportion between the space occupied by its blood-vessels and that occupied by its extravascular material; (3) the rapidity with which its vessels are traversed by the blood; (4) the greater or less extent to which heat is dissipated from it by conduction, by evaporation, or otherwise.

Of these conditions the most liable to great fluctuations are the second and third. We have already seen that the vessels of an inflamed part are dilated. That the flow of blood through an inflamed part is much augmented has long been suspected. Sir William Lawrence is said to have roughly demonstrated this long ago by bleeding from both arms simultaneously a patient whose hand and forearm on one side were inflamed. But Cohnheim firmly established the same fact by careful experiments. Having set up inflammation in the paw of a dog, he measured the amount of blood which afterwards escaped through a cannula from the principal vein of the limb; and he found that it was sometimes more than twice as much as flowed from a corresponding vein on the opposite side in the same length of time. The only exceptions were, when extensive gangrene set in, and when there was very profuse suppuration. Any such increased velocity in the blood-current of an inflamed part must necessarily raise its temperature.*

The second of the conditions above mentioned explains why sometimes an inflamed part is not apparently hot. When profuse suppuration was going on in a dog's paw there was sometimes no excess of blood flowing through its vessels. No wonder, therefore, that in cases in which the inflammatory process runs its course slowly, one occasionally meets with what is termed "cold abscesses." But it is unlikely that even they can develop from beginning to end without any elevation of temperature.

Varieties of exudation.—Inflammatory exudation presents many differences, according to circumstances which are as yet but imperfectly known.

In some cases, usually when a serous membrane is the seat of inflam-

* No doubt if superficial vessels are involved in the inflammatory process, more heat is at the same time dissipated, and this tends to prevent the surface temperature from approaching that of the internal organs. But a point of considerable importance is that such an increased dissipation of heat actually makes the surface feel hotter to one's hand than it would otherwise feel.

mation, the exudation assumes the form of a solid fibrillated material—"plastic lymph," as it used to be called. This is no doubt the same substance as the fibrin of coagulated blood, and is formed in the same manner. When this, with the leucocytes contained in its meshes, seems, as in a dry pleurisy, to constitute the entire exudation, it must be formed very rapidly, for it appears as a thin uniform layer upon the sloping surface instead of accumulating in the more dependent parts of the serous cavity. But perhaps the whole of the exudation never does solidify; a fluid residue may have been removed by the active absorbing process which we have seen to be at work.

As Cohnheim remarks, we should expect beforehand that inflammatory exudation would always contain fibrinogen, since that substance is one of the constituents of the blood-plasma. Now, since white blood-corpuscles are certainly seldom absent, the question arises why fibrin, instead of being constantly present, is found principally in inflammation of certain structures—the serous and synovial membranes and the alveoli of the lungs.

As a matter of fact, we find great difference in the products as well as in the course of inflammation. The following are the chief varieties:

Catarrhal inflammation.—When mucous membranes are slightly inflamed, as from exposure to cold, they throw off an abundance of more or less altered epithelial cells. In the lungs or in the kidneys such "catarrhal products" are often seen in immense numbers; not only do they accumulate in and fill up the pulmonary alveoli or the renal tubes, but a great many of them are also carried away in the sputum or in the urine. The relation between catarrhal inflammation and inflammation in general raises a question of the greatest importance, especially in reference to tubercle, as we shall see hereafter.

We must at present suppose that the excessive formation of epithelial cells is a result of the greatly augmented supply of pabulum offered to them in the inflammatory exudation. A tissue which in normal circumstances is constantly undergoing renewal may fairly be supposed to be ready to grow still more actively when such a stimulus is supplied to it.

Serous inflammation.—When a joint or serous cavity is affected with inflammation of moderate severity, it pours out a transparent fluid which accumulates in its cavity. There may be a thin layer of fibrin upon the free surfaces of the membrane; or shreds and flocculent masses may be floating in the fluid. Sometimes not a trace of fibrin is to be seen; fibrinogen is present, but for some reason remains uncoagulated. Virchow many years ago pointed out that fluid effusion, after its removal from the pleura by paracentesis, would often throw down a coagulum of fibrin, and that if this were removed, a fresh one might form in the course of the following day, and so on for several days in succession.

Suppuration.—In the more intense inflammations of joints or serous membranes the exudation is purulent, and does not coagulate. Intermediate conditions, however, are frequent, in which the surfaces are coated with fibrin, while the cavity contains liquid pus; and in the pericardium pus unmixed with fibrin (plastic lymph) is seldom, if ever, seen. This, however, is an exception, for in the case of other serous membranes it may happen that every part of the surface retains its natural smoothness and lustre notwithstanding that pus is present in large amount.

The quantity of pus which collects in a large serous cavity, such as the pleura, is often enormous; and since it may be formed very rapidly the

question has sometimes been raised whether the blood could possibly have yielded a sufficient number of leucocytes. But, as Cohnheim remarks, this difficulty in reality applies far less to the emigration theory than to that of pus-formation by proliferation. It has been shown that while inflammation is going on, the blood throughout the body contains an excess of leucocytes; and, indeed, its well-known hyperinotic condition may be said to be nothing more than a rough illustration of the same fact. One can easily suppose that the lymph-glands and the spleen throw into the circulating fluid a largely increased supply of leucocytes to make up for the drain that is going on. At the same time it appears very probable that pus-cells may themselves multiply by fission. Dr. Thin has figured a dumbbell-shaped leucocyte which seemed to be dividing into two, from the inflamed cornea of a rabbit; and similar appearances have been observed in cold-blooded animals by Stricker, Klein, and Ranvier. Possibly, since leucocytes evidently must have nutriment to enable them to multiply, the absence or scarcity of fibrinogen in pus may be accounted for by its having been used up by the multiplying corpuscles.

Croupous exudation.—We have seen that the rarity of lymph upon the surface of mucous membranes is far from being a solitary breach of a general law for inflammatory exudations throughout the body. The exceptional frequency with which a fibrinous layer is found lining the higher air-passages may be due to the same unknown causes which render the alveoli of the lungs also capable of a "croupous" as well as of a "catarrhal" inflammation. In connection with this question certain points have recently been raised which deserve careful consideration. Cohnheim has drawn attention to the fact that in the interstices of the tissues generally, exudation seldom coagulates; and he has shown that this probably depends not upon the absence of fibrin-factors, but rather upon a controlling influence which living structures exert over coagulation in their immediate vicinity. It would follow that whenever we find solid exudation in the connective tissue of any part of the body or within the stroma of an organ, we may be sure that the vitality of the part was endangered, if not lost, before coagulation took place. Now, there is an important class of inflammations in which the exudation of fibrin is thus associated with a local death of the inflamed structures. Wertheim asserted that a destruction of the epithelium of the trachea is a necessary antecedent to the development of a false membrane in the trachea, both in animals under experiment and in the human subject during disease.*

Diphtheritic inflammation.—The processes which combine fibrinous exudation with loss of vitality in the affected tissues are those which morbid anatomists now call "diphtheritic." The term is an unfortunate one, since it suggests an impression that they are connected with the disease Diphtheria, whereas this is by no means generally the case. Still we cannot avoid using it till a better name is found, for the condition is one which demands recognition. It is that in which a free surface, usually a mucous membrane, becomes coated with an adherent layer which in part at least consists of the upper strata of the mucous membrane itself, infiltrated with a fibrinous material. The distinction between a *croupous* and *diphtheritic* false membrane

* So far as I know, the suggestion has not yet been made that the endothelium of a serous cavity must die before a layer of plastic lymph can be formed upon it. Yet surely inflammatory exudation is far less removed from the influence of living structures when it is contained in the pleural or peritoneal cavities than when it is free upon a mucous surface.—C. H. F.

is not merely, as was formerly taught, that the one is easily separable while the other is firmly attached. It is chiefly in the air-passages, where there is a thick basement-membrane, that fibrinous exudations lie loose; upon the fauces and elsewhere they often adhere closely, if their fibrillation is dense and strong. A surface affected with diphtheritic inflammation looks dry, and is of a slate grey or pale yellowish colour unless it has been accidentally stained by a coloured fluid, such as bile. It feels rough and granular, and a still more marked character is its tough elastic hardness. In the dead body, if an incision is made into a diphtheritic membrane, the dry grey appearance is found to penetrate to some depth and to cease somewhat abruptly. Under the microscope is to be seen a granular, more or less distinctly fibrillated substance, containing in its meshes altered epithelial cells, and leucocytes which have lost their nuclei. In the more superficial part of such a false membrane the fibrin is often developed into thick and glistening fibres; in the deeper layers, where it is infiltrating the interstices of a pre-existing tissue, it has no room to show even fibrillation, and it looks granular. As we have already shown, so much of the substance of the part as is involved in the diphtheritic process has already lost its vitality, and the only way in which the disease can end (unless it destroys the life of the patient) is by the separation and shedding of all the dead tissues, with the false membrane of which they form a part. This detachment is effected by *ulceration*. From the first there was an inflammatory action of more or less intensity in the living structures beneath. But now leucocytes collect in large numbers along the boundary line, and probably the connecting material is directly eaten away and absorbed by them. Perhaps the best specimens of the shedding of an extensive diphtheritic membrane are afforded by the urinary bladder. This organ is exceedingly liable to diphtheritic inflammation, which often involves the whole thickness of its mucous coat; and it is no uncommon thing for the *mucosa* to be cast off almost entire. An autopsy was lately made by the writer in the case of a woman from whose bladder during life a piece of considerable size had been removed. All the rest of the vesical mucous membrane lay loose, as a thick ash-grey substance, with markings on one surface corresponding with those of the hypertrophied muscular trabeculæ.

It is obvious that recovery from a diphtheritic inflammation, when possible at all, involves the regeneration of the tissue which has undergone destruction, or at least its replacement by cicatricial tissue. After the separation of a croupous membrane there is nothing to be renewed unless it is the epithelium.

Not only is diphtheritic inflammation characterised by loss of vitality of the affected tissues, but also by their putrefaction; as is shown by their dirty grey colour, and by the fœtid odour which they give off. Indeed, this form of inflammation is but one member of a group, which may properly receive the name of "putrid inflammations," and in many of which large masses of tissue undergo death—*mortification* or *gangrene*.

Gangrenous inflammation.—It is customary to describe several forms of gangrene, and to refer them to different causes; but the more one studies these supposed varieties the more difficult is it to regard the distinction between them as fundamental. Of course, it is true that a part may be directly killed in various ways without the intervention of inflammation; as, for instance, by escharotics or by certain degrees of either heat or cold, according to the length of time during which they are in operation.

But in every case it is probable that a less intense application of the destroying agent would set up a violent inflammation, which itself would end in gangrene. So, again, when the death of a part is due to a failure of its blood supply, no doubt it does not always first undergo inflammation throughout its whole substance. Here, also, it seems impossible to draw a hard and fast line. Surgeons are now familiar with the fact that in many instances senile gangrene of the foot, which used to be attributed merely to obstruction of the arteries, arises from slight injury to a toenail, and begins as an inflammatory process. Even when a limb undergoes mortification as the direct result of embolism of its main artery, there is always at the margin of the gangrenous part, active inflammation, which leads to a further death of the tissues. Indeed, Cohnheim showed that the effects of a temporary ligature applied round the ear of a rabbit depend entirely upon the duration of the constriction. After a certain length of time the blood fails to penetrate into the vessels when the ligature is removed, and the part dies; but in other experiments, which were terminated at earlier periods, the result was only an intense inflammatory swelling of the ear with hæmorrhages into it. Lastly, in those forms of gangrene which seem to be determined by the occurrence of pressure—whether directly, by its lowering the vitality of the tissues, or indirectly, by its cutting off the blood-stream through them—there are always further conditions: a previous enfeeblement of the circulation, and some slight local injury which under normal conditions would have produced no appreciable ill-effects. Thus, bedsores occur chiefly in those cases in which there is also a marked tendency to hypostatic congestion of every dependent part, and the gangrene is preceded by inflammation that can be attributed to such causes as irritation of the skin by excreta, or unavoidable bruising during washing and drying, or friction against folds in the sheets. Thus, if we exclude what may be termed the immediate or instantaneous occurrence of gangrene, all its forms may be said to arise out of an inflammatory process.

We have seen that putrefaction is an essential part of gangrene. But in different cases there are great variations in the rate at which chemical changes in a dead tissue advance, and in the degree of fœtor produced by them. In the "senile" form of gangrene, the affected parts dry up and shrivel into a hard material like that of a mummy; and "dry" gangrene was formerly described as the characteristic effect of obstruction of the arterial blood supply. But it is now known that the desiccation depends upon the escape of fluid from the surface in consequence of detachment of the epidermis. It is only when mortification spreads very slowly indeed through the more massive segments of a limb that they can "mummify." The gangrene which ensues upon embolism of a large artery is more or less moist. But it often happens that deep structures remain soft, while superficial ones dry up into a horny mass, which is then termed an *eschar*. The colour of gangrenous parts is generally greenish or purplish black, but sometimes grey; it is due to chemical changes in pigment which has escaped from the blood-discs and has diffused itself through the tissues. The horrible odours so often emitted are attributed to the formation of sulphuretted hydrogen and volatile fatty acids. Gases frequently collect to such an extent as to render mortified tissues emphysematous, so that they crackle or "crepitate" when they are touched. In other cases they are saturated with a dark, thick, red fluid, which perhaps raises the cuticle into bullæ. That structures which have undergone mortification are com-

pletely devoid of sensibility and of any other vital function, is a matter of course. They also feel cold, since their supply of warmth is cut off with their supply of blood; but it is to be noted that very superficial patches of cutaneous gangrene sometimes receive so much heat by conduction from the subjacent textures, that their temperature scarcely appears lower than that of the skin in their neighbourhood.

Gangrene is often from the first "circumscribed," or limited to a certain part, and even when it spreads from one spot to another, its progress—if indeed the patient's life is saved—is at last always arrested. A "line of demarcation," as it is termed, is then formed. Here active inflammation develops, abundant exudation of leucocytes takes place, and the connection between the living and the dead tissues is gradually eaten away, until the latter become completely detached and are cast off.

Hitherto we have been regarding the different characters of inflammatory exudation as consequences either of special tendencies which we find to be manifested by the several tissues, or of the greater or less intensity of the irritation by which the inflammatory process was set up. There is, however, another side to this question. Many years ago Sir James Paget examined the fluid contained in blisters raised by the application of cantharides to the skin, in thirty patients of St Bartholomew's Hospital. In some cases it formed a firm, elastic, fibrinous coagulum, in others it was purulent. The former condition was observed in persons who were in sound health, the latter in those who were suffering from advanced phthisis or a similar disease. And, with a little practice, he found himself able to form an opinion, from the contents of a blister, as to the degree to which the person was cachectic, and as to the extent to which inflammation in him would tend to be "adhesive" or "suppurative." Again, in those who are suffering from Bright's disease it is well known that the exudation produced by even slight inflammations is apt to be very profuse and watery. Lassar found, by direct experiment, that when hydræmia was produced by the free injection of a saline solution into the veins of a dog, in whose paw inflammation had previously been set up, the lymph which escaped from the lymphatics of the limb became much increased, while the amount of solid matters in it was as greatly lowered. Moreover, patients affected with dropsy from renal disease are especially liable to gangrenous forms of inflammation, and the same thing may be said of those who labour under diabetes.

Events of inflammation.—Up to this point we have been dealing with the advance of the inflammatory process. But, except when it is cut short by the death of the patient, it always sooner or later enters upon a further stage, one of *subsidence* and *repair*.

If the inflammation is but slight, and if its exciting cause does not continue in operation, it may end directly in what is termed *resolution*. The circulation through the vessels of the affected parts then gradually resumes its natural condition; any leucocytes which may have escaped into the tissues pass away through the lymphatic channels; and any solid exudation that may have formed undergoes conversion into a fatty emulsion, which is likewise carried off in the lymph-stream.

On the other hand, if pus-cells have accumulated in large quantities in a serous cavity, or in the sac of an abscess, and are not removed by a natural or artificial opening, they die there and break up into granules. The fluid belonging to them is then absorbed, while the solid matters remain as an

opaque yellowish mass. This process is known as *caseation;* it is one to which we shall frequently have occasion to allude. Such cheesy residues are supposed by many pathologists to be incapable of undergoing further absorption; but this is very doubtful. They often become the seat of deposits of earthy salts, which give to them the consistence of mortar, or may render them as hard as bone. The tissues which surround them also present formative changes; but these may often be regarded as the result of fresh irritation set up by the dead caseating masses, which act as "foreign bodies."

In all other cases, the *formation of new tissues* constitutes a direct and essential part of the subsidence of inflammation. When a slough or an eschar becomes detached, or when an abscess discharges its pus, a hollow space is left, which is filled up by a process of growth. And even where the morbid change does not go beyond the exudation of plastic lymph this is often to some extent developed into a permanent structure. The steps by which this is brought about were studied with remarkable success by Ziegler in 1876. He embedded in the subcutaneous tissues of dogs a series of minute flat chambers, each consisting of a pair of glass plates, with a capillary space between them, cemented together at the corners, but open at the sides. These he removed after an interval, and found not only that leucocytes had penetrated into the space between the plates, but sometimes that tissue elements and even blood-vessels had developed there. The earliest step was the formation of large granular cells with vesicular nuclei. These he termed "epithelioid" cells on account of their appearance. They are generally round, but sometimes oval or irregular in shape. Their size is very variable, but sometimes they are larger than the epithelial cells of the tongue. They evidently arise out of leucocytes, which appear to grow at the expense of other leucocytes. Indeed, some go on developing until they become what are termed *giant-cells*—irregular masses of protoplasm, each containing a large number of nuclei. That these also are formed by the growth of a single cell, which destroys several others, there is no reason to doubt. In support of this view Ziegler lays stress on the fact that they are constantly found surrounded by an empty space. At first, he supposed that all the nuclei of a giant-cell were developed by fission from the nucleus of the leucocyte in which it had its origin; but he has since admitted that the nuclei of the absorbed cells may perhaps persist in it. Another feature of some of Ziegler's preparations is a *reticulum*, forming sharply outlined septa round the individual cells.

The "epithelioid" cells become pear-shaped or fusiform, and give off bundles of delicate fibrils. These fibrils assume parallel directions, and ultimately their extremities unite with those of fibrils derived from other cells. There is, however, one condition which appears to be essential to such a result; namely the development of blood-vessels in the exudation. They seem to arise partly as buds and loops from the sides of already existing capillaries, partly out of rows of cells, placed end to end, so as to open into one another, and form hollow tubes.

When much suppuration occurred round Ziegler's glass chambers, no formative changes were discernible in them. This corresponds with the well-known fact that only fibrinous effusions into a serous cavity are capable of organisation. It is particularly to be observed that in speaking of "plastic lymph" as undergoing development into connective tissue and vessels one means, not the fibrin itself, but the cells that are included in it.

In human pathology it is chiefly by the study of granulations that one has

an opportunity of observing formative changes originate in leucocytes; but Cohnheim speaks of large round or elliptical cells or even cells with many nuclei, as being generally discernible in small numbers in the pus which is discharged from a wound or an abscess of not less than a week's standing.

The connective tissue which is developed out of inflammatory exudation is sometimes of an enormous thickness, as in the pleura. It very slowly reaches its permanent condition. At first it contains no elastic fibres; according to Paget, they may appear as long as twelve months after its first formation. Lymphatic channels in the false membrane were described by Van der Kolk. In the cardiac valves, amorphous calcareous matter may be deposited in large quantity.

Inflammatory adhesions and cicatrices have a strong tendency to contract, and this may entail serious consequences if vital organs are concerned. On the other hand, adhesions sometimes after a long time relax and soften, even if they do not altogether disappear. Paget cites the following observation of Bichat's: a man had made from twelve to fifteen attempts at suicide, at different times, by stabbing himself in the abdomen. In the situation of the more recent wounds it was found that the intestines adhered to the parietes; but the adhesions corresponding with the older ones were reduced to narrow bands, or had even become divided and were hanging free. In cicatrices also a marked "loosening" may at length take place. These facts, and others, like the ultimate subsidence of sclerodermia, deserve to be borne in mind in reference to analogous changes in internal organs, which we are too apt to regard as hopelessly permanent.

The development of *epithelium* during the subsidence of inflammation is a necessary step in the process, not only after ulceration of the skin or of a mucous membrane, but in many other circumstances. That the cuticle which ultimately covers a granulating wound always arises in contact with pre-existing epidermis is well known; Reverdin's practice of skin-grafting is an interesting illustration of it. This fact does not prove that epithelial cells are always developed out of cells of the same kind; it might be explained upon Rindfleisch's hypothesis of "epithelial infection," the existing epithelial cells being supposed to influence the adjacent granulation tissue, so as to lead its cells to grow into epithelium. Most pathologists, however, now teach that it is impossible for leucocytes, which belong to the mesoblast to form epithelial cells, which are constituents of the upper and lower layers of the embryo.

Local varieties of Inflammation.—It will be well to summarise the various forms which inflammation assumes according to the organs which it affects.

1. The skin is very readily liable to inflammation. This may be slight and transient without visible exudation; or the exudation may produce general swelling—*inflammatory œdema;* or the exudation may appear as clear plasma in vesicles, bullæ, or on a raw weeping surface. Or the exudation may become rich in corpuscles and pustules; pus will result, with the formation of scabs when the pus dries up. Or the inflammation may be chronic and lead to fibroid thickening from "hyperplasia" of the deeper parts of the skin. When similar proliferation affects the inflamed epidermis, epithelial scales instead of spindle-cells and fibrous tissues are produced, and the inflammation becomes desquamative. Or the inflammation may be destructive, and cause loss of substance in the form of *ulceration.*

If this is rapidly progressive it is called *phagedæna*. If visible fragments of dead tissue result it is called, not molecular necrosis or ulceration, but *gangrene* or necrosis in mass.

2. The mucous membranes rarely form vesicles or pustules. Serous exudation, with more or less admixture of pus, is combined with mucin and with desquamation of the superficial epithelium. The whole process is called *catarrhal* inflammation, and the exudation mucous or muco-purulent, or purulent. This is the characteristic form of inflammation of mucous membranes, and the term catarrhal is best kept for it, although it has been extended to any watery discharge, such as the exudation of serous inflammation. Under certain conditions some mucous membranes are liable to a plastic or *membranous* form of exudation. This may affect the respiratory surfaces, including the larynx, pharynx, and fauces, nasal fossæ and conjunctiva, and the trachea and bronchi; it scarcely occurs elsewhere, and even here only during childhood or under special circumstances in adult life.

Again, mucous membranes are very liable to *ulceration*, especially the mouth, stomach, colon, rectum, and larynx. Much less frequently they exhibit the peculiar mixture of plastic and gangrenous inflammation, which has been called *diphtheritic* (p. 52), and which is rarely seen except in the fauces and larynx, in the large intestine, and less frequently in the bladder and uterus.

3. The serous membranes exhibit serous inflammation or plastic inflammation, or, more frequently, a mixture of the two. Occasionally, especially in children, the exudation is purulent; but in many cases this is due to infection with septic bacteria. The membranes lining the great pleuro-peritoneal sac—pleura, pericardium, peritoneum, and tunica vaginalis are also liable to chronic plastic inflammation with adhesions and thickening. Other surfaces covered by endothelium and hollowed out of mesoblast also undergo plastic inflammation. These are the lining membrane of the heart and arteries (endocardium and intima), the air-vesicles of the lungs, and the iris; also, under some conditions, the urinary tubules.

4. Connective tissues. Areolar tissue is readily susceptible of suppuration; but this is almost always secondary to pustules or ulceration of the skin, or perforating abscesses from internal cavities, or general pyæmia. It is also liable to acute serous exudation, as in the anasarca of Bright's disease. Fat very rarely inflames—tendons scarcely ever; ligaments only from strains and ruptures, or from synovitis.

5. Cartilage is little liable to inflame, but is capable of ulceration—chronic or acute and infective; it also may undergo interstitial inflammatory changes, which make it opaque and calcareous. The cornea resembles articular cartilage in its inflammations, which are either acute and ulcerative or chronic and interstitial. The fibro-cartilages, both yellow and white, seem almost exempt from inflammation.

6. Bone is frequently attacked by acute suppurative inflammation, which usually leads to death, either molecular ulceration or caries, or else massive sloughing or necrosis. The chronic inflammation of bone is characterised by hardening (osteoporosis), with hypertrophy and obliteration of the cancelli.

7. Muscles are rarely liable to inflammation, and probably never to suppuration. Myocarditis leads to fatty degeneration. Chronic inflammation of the muscles is supposed to be the cause of myalgia, or muscular rheumatism.

8. Peripheral nerves are almost exempt from suppuration. Neuritis, whether parenchymatous or interstitial in origin, ends in thickening of the perineurium and destruction of the myelin.

9. The solid viscera are liable to three chief varieties of inflammation. These are :

a. Infective, suppurative, traumatic or secondary (usually bacterial), acute.

β. Idiopathic, non-suppurative, parenchymatous, softening, acute or subacute, varying with each organ.

γ. Interstitial, fibroid, contracting, hardening, chronic, and insidious.

Under the first head come abscess of the brain (usually from caries or pyæmia), pyæmic pneumonia, abscess of the liver, "surgical" kidney, and pyæmic abscess of the spleen.

Under the second—it is doubtful whether the acute red softening of the brain is inflammatory or hæmorrhagic, and whether acute myelitis is always truly inflammatory ; but some cases of the latter are proved to be so by the meningitis which goes with them. True acute lobar fibrinous pneumonia is the typical instance of this group ; but its inflammatory nature has also been called in question ; at least it is never traumatic, or suppurative, or chronic. Acute yellow atrophy of the liver should probably be classed as a diffuse parenchymatous hepatitis. Glomerular and tubal nephritis, acute, subacute, and chronic, belong to the same group. The spleen does not appear liable to a similar affection, nor the lymph-glands, nor the testes, nor the ovary.

Under the third head falls the grey degeneration or, as it is now called, sclerosis (hardening and shrinking) of the brain and spinal cord, varying in its symptoms according to its locality, but always showing the same histological features. The corresponding process in the lung is chronic interstitial pneumonia, iron-grey induration with contraction, sometimes called cirrhosis. That in the liver is the chronic interstitial hepatitis named cirrhosis by Laennec. That in the kidneys is the chronic intestinal form of Bright's disease. A very similar process is seen in the fibroid testis, which results from chronic syphilitic orchitis, and which, when gummata are also present, closely resembles syphilitic cirrhosis of the liver.

Ætiology.—With regard to the causes of inflammation in general little need be said in the present chapter ; they will be discussed hereafter in detail. It must be pointed out, that the analogy of the pathological processes concerned, compels us to classify as inflammatory a large number of affections in which we cannot directly recognise the operation of any irritant upon the vessels or the tissues. How internal inflammations are caused by exposure to cold we do not know. That cold often excites pleurisy, pneumonia, myelitis, nephritis, and many catarrhal affections, is generally admitted. But probably there is no general principle to which their ætiology can be referred, so that the relation between these several diseases and their cause is different for each one. A point of importance is that there are some organs and tissues which, so far as we know, are not capable of inflammation as the result of cold. This is true of the brain, and, with few exceptions, of the peritoneum. The same remark applies to the pericardium and to the liver, spleen, adrenals, testes, and ovaries. Of the mucous membranes, those of the entire respiratory tract, including the conjunctiva, frontal sinuses, larynx and bronchi, are most prone to inflammation "from cold ;" next the fauces and intestines ; rarely the bladder ; while the mouth, œsophagus, and stomach are exempt.

There can be no doubt, however, that many inflammations depend only in part upon the external cause that excites them ; the larger share of their

ætiology belongs to what may be fairly termed a "predisposing" morbid condition of the tissue itself or of its blood-vessels. It would seem that this has an important bearing upon the way in which some inflammations spread from point to point, and even from tissue to tissue, without decrease in their severity. When an irritant is applied to any part of the body its effects may extend for some little distance beyond, but their intensity rapidly diminishes—unless, indeed, the resulting morbid process belongs to a separate group of affections, those which are "septic" or "infective." But many inflammations not obviously traceable to an external cause diffuse themselves very widely. For instance, we may find pleurisy complicated with pericarditis or peritonitis, pneumonia leading to meningitis or to nephritis, and so on. In one remarkable case, a boy was admitted into Guy's Hospital under Dr Taylor for what at first appeared to be meningitis, but a day or two later the symptoms seemed rather to be those of peritonitis. After death the oldest lesion was found to be a chronic pericarditis, probably of three or four weeks' standing; but in addition there was acute pleurisy, diffused acute peritonitis, and equally universal acute meningitis. In no part of the body was there any trace of tubercles, or even of caseation.

CHRONIC INFLAMMATION AND GRANULOMA.—We have seen how difficult it is to draw a clear line between acute and chronic inflammation on the one hand, and between chronic inflammation and hypertrophy or fibroid degeneration on the other.

There is, however, another form of chronic inflammation which ends not in fibrous thickening or hypertrophy, but in the formation of a new growth of cellular tissue which resembles the granulations of an ulcer. This process appears to be intermediate between inflammation and the production of neoplasm or tumours, and the diseases which come under this head were included by Virchow in his great work on morbid growths. Anatomically they consist of young spheroidal cells (leucocytes), often with "epithelioid" and "giant-cells" among them. There is no fibrous tissue and a rather scanty vascular supply.

The term *infective granuloma*, which is now commonly applied to the pathological group in question, includes Tubercle, Lupus, Syphilis, and the rarer forms of disease known as Glanders and Leprosy. They all agree in their histological characters, and more or less in their clinical course. We now know, moreover, that they owe their peculiarities to the presence of microphytes which act as permanent irritants and keep up a "specific" form of inflammation. This interesting pathological group has therefore relations to inflammation in one aspect, to contagion and microbes, and so to specific fevers, in another, and to tumours and neoplasms in a third.

Its several members will be discussed hereafter. Tuberculosis and syphilis will take their place among specific febrile diseases, inasmuch as apart from the local granuloma there is pyrexia from infection (or as the French pathologists call it, "intoxication") of the whole body by the microbes conveyed in the blood.

Glanders combines local inflammation of a granuloma-type, specific infection, generalisation and fever, and, as a matter of convenience, will be described under the general head of specific fevers along with others of animal origin.

Lupus and leprosy, however widely spread, continue local diseases, and will be noticed among affections of the skin.

PYÆMIA

Putrefaction in wounds may be avoided without excluding the air, by dressing them with some agent capable of destroying the vitality of the atmospheric organisms, provided that it does not act with too great violence upon the human tissues.—LISTER.

Theories of pyæmia—Metastasis—Phlebitis—Septicæmia—Embolism—Infection—Microphytes—Practical application—External or traumatic and internal pyæmia—Channels of infection—Local distribution of secondary abscesses—Idiopathic pyæmia—Slighter forms—Diagnosis: especially from enteric fever and tuberculosis—Prognosis—Treatment.

IT is remarkable that so little attention was formerly paid to the malignant process which often rendered slight wounds and injuries mortal, and which up to the present day was the great danger to be feared after the most skilful surgical operations. The very names of blood-poisoning, septicæmia, and pyæmia are recent, while tetanus, the far rarer sequel of wounds and injuries, was familiar from ancient times.

Probably one reason for this was that the immediate effect of wounds in producing what was called "irritative fever" was confounded with the later appearance of pyæmia, and that this was not distinguished from the still later "hectic" (*i. e.* continued) fever which accompanied prolonged suppuration. Another reason may have been that in the hotter climates with which the physicians of ancient Greece were familiar (and those of Italy in the sixteenth and seventeenth centuries) cases of tetanus are more common than in the north of Europe. Lastly, whatever other miseries followed an ancient or mediæval battle, the wounded were at least free from the dangers which made the crowded wards of a city hospital, until recent times, a hotbed of pyæmia.

Pyæmia (wound-fever, surgical infection) is happily of much diminished practical interest to the modern surgeon; but its pathological interest is as great as ever, and it enters so far into certain forms of internal disease that a treatise on the principles of medicine would be incomplete without some notice of this general morbid process. Its place is naturally after inflammation and infection and before specific contagious diseases.

Theory of pyæmia.—When an unhealthy-looking wound was accompanied by fever, with wasting, sweats, and more or less jaundiced tint of skin, the earlier pathologists supposed that an "ill-habit of body" prevented the wound from healing; and when abscesses were discovered after death in the lungs, liver, and other organs, they were ascribed to *metastasis* or transference of "disease" or "inflammation" from the wound to the internal organs. Even the strongest humoralists seem not to have supposed that the ill-habit of body was due to poisonous humours absorbed from the wound.

The first attempt to ascertain the exact nature of the process of pyæmia was made by Cruveilhier. He believed it to depend upon *suppurative*

phlebitis, which Hunter had long before (1784) distinguished from adhesive phlebitis.* Hence, for many years surgeons dreaded injury or even ligature of veins.

One of the achievements of Virchow was to discover the true meaning of this phlegmonous, suppurative, or infective phlebitis. He showed that what was supposed to be a mass of pus-corpuscles, the product of inflammation in the lining tunic of a vein, is really a discoloured clot composed of leucocytes and fibrin. He showed that fragments of this clot may be detached and carried by the still open veins to the right side of the heart and thence to the lungs; and that in like manner *thrombi* (*coagula*, clots) may be carried from the right side of the heart to the lungs and thence to the systemic capillaries. This remarkable process of *embolism*, by which detached particles of clot are carried from the original *thrombus* by the blood-stream, had been independently discovered by Dr Kirkes, of St Bartholomew's Hospital. It was extended by the great pathologist of Berlin not only to explain the mechanical effects of a plug of fibrin, but also the more dangerous results when the emboli are derived from a septic or putrid thrombus and act not only as mechanical obstructions to the blood-vessel in which they lodged, but also as centres of infection to the surrounding tissues. The mechanical effect of emboli upon the hydraulics of the circulation will come under consideration when embolism of the cerebral arteries is discussed. It is of practical importance in this case, and also when it occurs in the retina, in the kidney, or in the spleen; and it is most important of all when it affects the lesser circulation and obstructs a main branch of the pulmonary artery. When the clot is septic, two pathological processes are combined, the mechanical effects of the embolism and the infective power of the poisonous embolus. This latter condition was distinguished by Virchow as *septicæmia*.

Previously, the effects of pyæmia had been ascribed to actual contamination of the blood by pus. But when pus-cells were ascertained to be only, as Virchow believed, young cells, like white blood-corpuscles, or, as we have seen in the last chapter they are now proved to be, true blood-corpuscles out of place, it was clear that the mere presence of these elements in the blood could no longer explain the process of pyæmia. Moreover, as Virchow had proved, the white cells found in the thrombus were not pus (for they had never left their habitation), but leucocytes aggregated by coagulation and not by inflammation. Accordingly, various terms, such as septicæmia, ichorræmia, and saprræmia (since applied in a special sense) were invented or adopted from earlier pathology to express the element of "blood-poisoning" which complicated that of embolism.

In this as in other departments of pathology, direct experiment upon the lower animals was at once the herald and the guide of speculation,—speculation based on the exact facts of minute anatomy, and controlled by clinical experience. It was found, first, that minute fragments of healthy blood-clot, introduced into the circulation, acted like seeds or any other non-irritant foreign bodies as mechanical obstructions leading to anæmia, to hæmorrhage, and other local results, but not to suppuration or to fever. Secondly, it was found that pure *pus laudabile* when injected into a vein either mingled with the blood, the corpuscles gradually breaking up and no effect following, or if

* The refutation of the hypothesis that suppurative phlebitis spread by continuity from the wound to the heart, was due to Arnott and Dance, who wrote before 1830. See Virchow's 'Gesammelte Abhandlungen,' S. 637.

in large quantity formed an ordinary non-infective thrombus. Thus "pyæmia" was proved not to be what the name signified, pus in the blood. Cruveilhier had before ascertained that globules of mercury when injected acted as irritants and produced inflammation and abscess around the point where they stuck in the capillaries. Thirdly, it was found that when ichorous, putrid, unhealthy pus, carefully filtered so as to get rid of all fragments of solid matter, or even dialysed so as to leave corpuscles and most of the albumen and globulin behind, was injected into a vein, the result was increased temperature, disturbance of the nervous system, diarrhœa and congestion of the lungs; but neither during life nor on dissection after death were "metastatic" abscesses discovered, nor lobular pneumonia nor embolic "wedges."

Thus the result of observation and experiment up to a recent date was that pyæmia or wound-fever was not due to "metastasis" of suppuration from the seat of injury to internal organs; that it was not due to suppurative, still less to ordinary adhesive phlebitis; that it was not due to the entrance of pus into the blood nor to mere embolism, nor to poisoning of the blood with chemical compounds in solution—such alkaline products as have lately been recognised as ptomaines; but that it was made up of two pathological processes, embolism and septicæmia. An infective or septic thrombus gives rise to infective emboli, and these reproduce the parent suppuration, not by a mere deposit of pus, but by acting as an irritant and exciting around them as foci true inflammation which ends in the formation of pus. Every "pyæmic" abscess of the lungs is preceded by lobular pneumonia, every such abscess of the liver or kidneys by corresponding inflammation. The "secondary" abscesses resemble the primary suppuration as the secondary "deposits" of cancer resemble the primary tumour.

But all these observations and experiments were, in the words of Bacon, "light-bearing" rather than "fruit-bearing." Knowledge of the process of pyæmia had come, but power to prevent it lingered. The mortality from pyæmia after operations in well-ventilated, cleanly hospitals was grievous, but in hospitals like the old Hôtel Dieu, of Paris, or the old hospital at Halle, it was terrific. In order to avoid this dreaded scourge, the most elaborate dressings were devised, as complicated, as cumbersome, and as useless as the armour of the fifteenth century; breasts were removed by *cautérisation à flèches*, wedges of chloride of zinc were thrust into the tissues and allowed to eat away the organ, tumours were grubbed out with the fingers, and even limbs were amputated by an *écraseur*. Meantime, thoughtful surgeons noted that pyæmia, so fearful under all the appliances of great cities and the dexterity of the most skilful operators, was far less frequent in country places, in open tents and in cottage hospitals.

At length the explanation came. It was not access of air, nor of oxygen, nor of pus, nor of ptomaines, but it was the invasion of certain lowly-organised plants which made the utmost skill and the most elaborate precautions unavailing, and which had almost led some distinguished surgeons to abjure operations altogether. A brief account of these microphytes was given in the chapter on Contagion. They have been divided by their physiological effects, rather for convenience than as a scientific distinction, into those which are fermentative, those which secrete pigment, those which give rise to specific diseases and those which produce putrefaction. The members of the last group, the septic bacteria and micrococci, are those which cause pyæmia. When they are precluded from gaining access to a wound, no infective thrombi

are formed, no septicæmia occurs, no fever results, and no secondary abscesses are produced.

The recognition and classification of these perilous microscopic organisms was the work of many observers, microscopists and botanists, physiologists and pathologists. The application of this knowledge to the practical end of preventing the mischief they do was due to the scientific training and the philosophical insight, the skilful ingenuity and the untiring efforts towards perfection of methods which enabled our illustrious surgeon, Lister, to effect a revolution in practice.

Pyæmia, then, though like other terms it may be retained when its original significance has been disproved, is a somewhat complex condition. It combines (1) septicæmia or absorption of chemical soluble products, themselves probably the result of the action of septic bacteria; (2) thrombosis and embolism or transference of minute clots from the veins to the lungs and thence to the systemic capillaries; (3) the presence of infective bacteria, surviving their transference in the blood-stream and propagating in the spot to which they are conveyed; (4) local inflammation of a putrid, infective, and virulent character, which leads to (5) necrosis and abscess.

Probably the local determination of a pyæmic focus is often determined by the size of the capillaries of the part; those of the lung are comparatively large, and transmit objects which will block the far more minute vessels of the joints. But beside this, Drs Wilks and Moxon ('Path. Anat.,' p. 626) argue with much force, and from large experience, that local stagnation (as in the back of the lung when a patient is in bed, in the cerebral sinuses, in the large veins of the prostate, and in the recesses of the valves of veins) will cause an accumulation of infective particles, and thus determine the local foci of their earliest and greatest activity.

Internal pyæmia.—In the great majority of cases pyæmia results from an external wound, accidental or operative, and so far it belongs to what is called surgical pathology rather than to internal medicine. But not unfrequently we meet with cases where the origin of the pyæmic process is internal and not traumatic. It is always a breach of surface; but it is not always a mechanical breach in the skin or accessible mucous membranes.

One variety of internal pyæmia, and the most important by its frequency, is when infection takes place from the uterus after delivery. The septic peritonitis and other pyæmic symptoms which follow the formation of septic thrombi in the great uterine sinuses, constitute one form of the dreaded puerperal fever; and here also antiseptic precautions have been introduced. Another form of internal pyæmia is when the origin of the process is in bones, most often in the petrosal bone of the skull; such cases will be described under diseases of the brain. A third depends on suppuration of the urinary tract, but this is most frequently the result of stone in the bladder or of stricture, diseases which admit of mechanical treatment; so that urinary pyæmia, or as it has been called, "erysipelatous," "diphtheritic," or "infective" inflammation of the urethra, bladder and kidney falls for the most part within the arbitrary limits of surgical pathology. Again, when there is suppuration in the alimentary canal (as in dysentery), a local or a general infection of the blood may result.

In most of these cases the primary seat of inflammation is more or less directly in communication with the exterior of the body, and therefore liable to contamination from bacteria on the surface. But in another remarkable

group of cases the original focus of infection is in the interior of the vascular system. These cases of ulcerative, infective, or malignant endocarditis are in the fullest sense internal pyæmia, and here, as was first shown by Professor Heiberg ('Virchow's Archiv,' Bd. lvi), the primary ulcer is characterised by the presence of septic micrococci. This remarkable variety of disease will be described under diseases of the heart in the second volume of this work. How microphytes gain entrance to the interior of the cardiac chambers is most difficult to understand, but not more so than their access to the bones in cases of acute osteo-myelitis.

Mode of infection.—The virulent, putrid or septic, bacterial inflammations which accompany pyæmia appear to spread in three ways:

(1) By continuity: chiefly seen in the case of mucous surfaces, as when a gonorrhœal urethritis extends to the bladder and then along the ureter to the pelvis of the kidney; or when scarlatinal angina passes along the Eustachian tube and infects the middle ear; or when septic metritis travels up the Fallopian tube to the peritoneum.

(2) By lymphatic channels: as when an unhealthy sore on the finger sets up inflammation of the lymphatics of the arm and causes a glandular abscess in the axilla. By a somewhat different route, but probably still by means of the large lymphatic channels which unite the areolæ of connective tissue with each other and with the great serous lymph-sacs of the body, an acute suppurative pleurisy spreads to the pericardium, or infective perimetritis to the peritoneum, or bacterial peritonitis to the pleura.

(3) By veins: in this process alone of the three, septicæmia and conveyance of septic organisms is combined with thrombosis and embolism. It is the commonest and most fatal of all forms of pyæmia. It may infect the veins of the extremities after amputation, the sinuses of the dura mater from caries of the bones of the skull, the portal system of veins from dysentery, and the systemic capillaries from ulcerative endocarditis.

Apart from these forms of local pyæmia, which can be explained by the anatomical relations of the parts involved, certain remarkable facts have been observed which appear to point to the great principle that, when morbid influences affect the whole body in common, each tissue and each organ has its own greater or less proclivity to suffer, and each has, to some extent, an individual power of modifying the general process when it is itself affected. We see this law in operation when the organs and tissues are affected by starvation, by overfeeding, by lead-poisoning, by alcohol, by the diseases which, like poisons, affect not the blood only but blood and bone and flesh —tubercle, syphilis and cancer, lardaceous and fatty degeneration, syphilis, scarlatina, and malaria. Every organ and tissue, every living cell in the body must be acted on by the same exciting agent in each of these diseases, but all react differently.

So with pyæmia. Percival Pott in the last century noticed that abscesses in the liver were particularly apt to follow injuries to the skull. The serous membranes suffer most in puerperal septicæmia. The lungs and liver are more prone to pyæmic suppuration than the brain. The pancreas and mamma and testis almost always escape. Arterial pyæmia affects the spleen and kidneys and brain and liver more often than other organs. Infection starting from a bone is most apt to produce secondary abscesses in the heart and in the kidneys, as Wilks and Moxon discovered.

Idiopathic pyæmia.—Ulcerative endocarditis, portal pyæmia, urinary

pyæmia, and cerebral pyæmia, with the results of infective caries of the vertebræ and pelvis, are the most frequent kinds of internal or, as it may be styled, "medical" pyæmia. Occasionally it results from an empyema or from some internal abscess, from typhlitis, or from sloughing ulceration of the fauces, the rectum, or the skin.

The most puzzling cases to account for are those which we are forced to call Idiopathic Pyæmia. It occasionally happens that on a *post-mortem* examination unmistakable signs of general infective embolism are found, lobular pneumonia with pulmonary abscesses, ecchymoses of the pleura and pericardium, staining of the inner surface of the aorta and multiple abscesses in the liver or kidneys or spleen, or suppuration in the joints; and yet it is impossible to discover the source of the infection. There is no external injury or wound, the urethra is found healthy, there are no anal fissures or inflamed piles, no chronic ulcer of the fauces or pharynx or nasal fossæ, no necrosis of the long bones, or caries of the vertebræ or ilium or internal ear. In one case, the late Dr Moxon, after laboriously searching these and other parts, extracted every tooth from its socket to make sure that there was no alveolar abscess or caries; yet all was in vain. Sometimes we are rewarded by discovering the source of the mischief in unexpected situations,—a pin or other foreign body in the appendix cæci, caries of the ethmoid bone or of the sacro-iliac joint, pyosalpinx as the result of gonorrhœal inflammation of the vagina. But in a few cases we are compelled at the end of the search to confess our failure and to call the case one of idiopathic or spontaneous pyæmia.

Whatever doubts may still be felt as to the possible origin *de novo* of infective diseases, such as enteric fever, scarcely any pathologist will admit that bacteria appear in the blood spontaneously. They must, either as minute micrococci, or possibly as still more minute bacterial spores, gain an entrance by some undiscovered breach of surface.

Slighter forms of pyæmia.—It is probable that under this head should be classed certain cases, common in surgical practice, and not unknown in the medical wards of a hospital, where a patient, suffering from some internal suppuration which has been relieved either naturally or by incision, is from time to time attacked by more or less marked rigors, rise of temperature, quick pulse, loss of appetite and sometimes profuse sweats. We can usually trace this to the flow of pus being interrupted, and when free exit is restored the symptoms disappear without further inconvenience.

Such accidents we see in the course of an empyema which has been opened, of purulent pyelitis, of suppurating hydatid of the liver, and of otorrhœa from caries of the petrosal bone. In many instances an abscess has been opened under strict antiseptic precautions, and there is no reason to suppose the entrance of impure air or secretions afterwards. The symptoms referred to are certainly connected with retention of pus and disappear when free discharge is established. They are quite different from the mere effects of pain when healthy secretions are retained, or when an over-full cyst or an inflamed testis produce general disturbance by pressure which disappears when the tension is relieved. Hence, these symptoms cannot be referred to the mechanical effects of pressure upon nerves. They seem more likely to be caused by the increased pressure leading on hydrostatic principles to entrance of chemical products of inflammation or possibly of septic organisms themselves into the adjacent lymph-spaces or blood-vessels.

Diagnosis.—The symptoms of pyæmia as it occurs after a surgical operation are happily less familiar to the present generation of medical students than before the introduction of antiseptic surgery. Still, however, they occasionally occur and are well recognised. The difficulty arises when no wound or injury is found to account for the symptoms.

These cases of internal or non-traumatic pyæmia present themselves to the physician under the form of fever, and pyrexia is the only constant symptom. It may be accompanied by local pains, by tenderness, or by œdema, which are of the utmost value in leading to the source of mischief. But these are often absent. Headache, delirium or stupor, muscular twitchings, diarrhœa, profuse sweats, a jaundiced tint, are none of them constant symptoms, and all may be present in cases of typhus, of enterica, or tuberculosis. Pain and swelling of the joints may also be present and simulate rheumatic fever. In cases of ulcerative endocarditis the cardiac murmurs with pyrexia sometimes make this last resemblance extremely close, and pericarditis and pleurisy may rather increase than diminish the difficulty of diagnosis, while the fact of previous attacks of rheumatism is far from making the more serious alternative unlikely. This difficulty will be discussed in the chapter on rheumatism in the second volume of this work. The age of the patient, the persistence of local synovitis, the presence of jaundice, and signs of embolism in the brain, spleen, kidneys, or retina, may more or less conclusively decide the diagnosis, but in some cases it is impossible to decide until time has developed the course of the disease. Moreover, rheumatism occurring repeatedly with concomitant lesions of the valves may at last appear in combination with a new and infective form of endocarditis.

The most characteristic single symptom of pyæmia is pyrexia, which is of a remittent type, rarely falling below normal, but rising suddenly and irregularly, to fall again with equal abruptness. It has none of the regular daily variations and steady general rise, culmination and subsidence which we observe in typhus, enterica, and the exanthems. It has not the regular evening rise of hectic fever, which in many respects it resembles, nor the frequent subnormal temperatures, alternating with irregular elevation, characteristic of some forms of acute tuberculosis. Hyperpyrexia is more common than in enteric fever or in phthisis. The resemblance to a regular form of remittent malarial fever is sometimes remarkably close and deceptive.

When a patient is found suffering from fever not due to external inflammation, we first ascertain the absence of internal acute disease, and especially of pneumonia and of phthisis. We may then have to await the appearance of a characteristic exanthem, as the rash of scarlatina, the mulberry eruption of typhus, or the erythematous blush of erysipelas—which is often delayed for a day or two after the temperature has risen. If the first week of fever has passed without these appearances, and if there are no physical signs of pneumonia—which sometimes only appear after two or three days of pyrexia—we then reconsider the possibility of enteric fever and of acute tuberculosis, and lastly the question of internal pyæmia.

Enterica usually begins insidiously, the temperature rises gradually, and the state of the tongue and of the bowels make diagnosis easy even before the rose rash appears. Occasionally it begins more abruptly, the temperature rises high in the first week, the rash is absent or has passed unnoticed before the patient was seen, the bowels are constipated, and diagnosis may then become extremely difficult.

Acute tuberculosis can usually be traced to previous tubercular disease of the lungs or lymph-glands or abdomen of which the signs remain in evidence, or we may find a caseous testis or symptoms of "strumous" pyelitis. Or we may have evidence of meningitis, or we may discover one or more tubercles in the choroid. The lungs are in these cases almost always the seat of disseminated tubercles, and this may be recognised, not so much by physical signs, which are often limited to a slight occasional rhonchus, but by the high ratio of respirations to pulse and temperature, by slight duskiness or marked cyanosis, by the alæ nasi working in aid of the chest, and by dyspnœa unaccounted for by examination of the chest.

When combined with tubercular enteritis in a child it may be almost impossible to distinguish acute tuberculosis from enteric fever, until the subsequent course of the disease makes its clear.

When we suspect pyæmia, our first investigation is directed to the ear for a purulent discharge, to any of the bones or joints which may be tender or œdematous, to the genito-urinary organs, and to the heart. Symptoms of pyæmia, with a cardiac murmur, point almost certainly to ulcerative endocarditis; this is the more probable if previous valvular disease has existed, and particularly if the febrile symptoms have come on during convalescence from pneumonia, as was stated by Dr Osler in his lectures before the College of Physicians, and the signs of embolism in other organs may confirm this diagnosis. In the rare case of this disease affecting the right side of the heart, of which we lately had an example in Philip Ward, the lungs are the first organs to be affected, and the diagnosis is comparatively easy. When infective emboli lodge in the spleen it becomes enlarged, partly by the formation of fibrinous wedges (*infarcta*), partly by the febrile intumescence of the whole organ.

The splenic dulness being increased and the viscus being felt below the ribs on inspiration, does not in itself distinguish the case of pyæmia from one of enteric fever or of ague, but the "typhoid spleen" and the "ague-cake" are not usually sensitive, while the pyæmic spleen is tender to the touch, probably by reason of acute local peritonitis. Hæmaturia, hemiplegia, and, above all, the presence of icterus would confirm the diagnosis.

When otorrhœa, especially fetid otorrhœa, with a perforated tympanic membrane, is present, we may often discover tenderness or œdema over the mastoid process or down the neck. The infection travels by the internal jugular vein to the heart, and then affects the lungs, setting up suppurative lobular pneumonia and acute pleurisy.

On the whole, it may be said that in most cases internal pyæmia has an origin which with care and patience can be discovered during life; that enterica is the most variable of all specific fevers in its course is most frequently unrecognised; and that in doubtful cases we may consider that "common things most commonly occur," or, to state a converse truism, that we rarely meet with rare diseases.

The following recent example of idiopathic pyæmia shows the difficulty of diagnosis, or at least the fact that a wrong diagnosis may be made.

A girl, twenty years of age, who had been confined four months earlier, was admitted into Mary Ward on December 6th, 1886. She was in high fever, with more or less constant delirium and severe headache, and photophobic. She had, we were told, complained only that morning, had gone out without eating her breakfast, and was found moaning and almost insensible in a corner of the room where she had gone to sell bottles to the

hospital patients. The pupils were contracted, there was broncho-pneumonia on both sides, and the temperature rose high, notwithstanding cold affusion and ice-bags, reaching 105·8°. She had, we afterwards learned, complained of headache three or four days before the attack began, but otherwise appeared to be in her usual health. Her mother and a brother had died of consumption. She was in a very dirty condition and her scalp was covered with scabs from *impetigo pedicularis*. When the temperature was 104·2°, the respirations were 44, and the pulse 120. Next day she was duller and lay curled up in bed. There was a faint apex-systolic murmur. On the third day a pleuritic rub was heard and the respirations rose to 54, with temperature 104·8°, and pulse 140. The next day the fever rose to its highest point and was once more reduced by ice; albumen appeared in the urine, and she died after three and a half days' illness. I supposed that she was suffering from acute tubercular meningitis with similar disease of the lungs. The brain, however, was found normal. There was recent plastic pleurisy and a vomica in the apex of the right lung, but no miliary tubercles in the lungs. There was no ulcerative endocarditis, but a little recent lymph on the mitral curtains. One small abscess was found on the surface of the liver. The spleen was swollen but contained no embolic foci. Both kidneys contained numerous small abscesses as in ascending pyelitis, but the pelves were normal, as were the ureter and bladder. The vagina, uterus, and Fallopian tubes were healthy; one ovary contained a serous cyst. The skull and internal ear, the sinuses, the vertebræ and sternum, and all the large joints were searched and all the internal organs, but nothing further was found except one small ulcer in the duodenum. The portal vein was perfectly normal.

Prognosis.—As a rule cases of internal pyæmia are hopeless, and the exceptions are very few. But there are cases, to which Sir James Paget has particularly drawn attention, of chronic pyæmia where the fever is never high, internal organs are spared, and the joints are successively attacked by suppuration. These cases sometimes recover, and it appears certain that some forms of bacterial infection can be dealt with successfully by the living leucocytes and tissues when the number of microphytes admitted is not too large. So that we may say that, even with our present means of treatment, pyæmia is not an absolutely fatal disease.

Treatment.—The indications are first to ascertain, if possible, the source of infection, and give free exit to the septic materials. When an empyema has been laid freely open and drained, a mastoid bone trephined and the pus given exit, a sequestrum of bone cut down upon, or a joint freely incised, infection may not only be avoided, but even a pyæmic process already begun may be prevented from becoming general. A second indication is the free exhibition of stimulants, quinine, and as much concentrated food as can be taken. Quinine in large doses is believed by many surgeons to have a "specific" as well as a "tonic" effect in pyæmia. It is possible that it may check the multiplication of microphytes, and we may one day find in perchloride of mercury, or some more harmless and energetic parasiticide, a more efficient means of dealing with even internal pyæmia than we at present possess.

TUMOURS

Καρκίνωμα ἐστὶν ὄγκος κακοήθης καὶ περίσκληρος, ἀνέλκωτος ἢ ἡλκώμενος· εἴρηται δὲ ἀπὸ τοῦ ζώου καρκίνωμα.—GALEN.

New growths—Innocent and malignant tumours—Virchow's characters of malignancy—Malignancy not an attribute of structure—Histological classification of tumours—Malignant osteoid tumour—Sarcoma: round, spindle, and giant cells; hæmorrhagic and alveolar sarcoma: melanotic sarcoma—Multiple sarcomata as a general disorder—Osteitis deformans—Lymphoma—Carcinoma—Heredity—Theory of new growths.

THE term Tumour was once applied in modern languages (as *tumor* in Latin) to all swellings which were not obviously inflammatory, so that it included hydroceles, retention-cysts of all kinds, hydatids, hypertrophies of the spleen, enlargements of the liver, and even the swelling of a dropsical limb. One of the first lessons in morbid anatomy was that circumscribed solid masses, like external wens, are to be met with in the internal organs as well as on the surface. From a pathological point of view these solid outgrowths were distinguished as *pseudoplasms*, *neoplasms*, or *new growths*. This conception of an independent centre of growth, as distinct from mere hypertrophies of existing tissue on the one hand and from inflammatory swelling on the other, still determines the character of a tumour in the modern sense.

When a tumour grows on mucous membrane, it often projects from the surface, and may hang by a distinct pedicle; it is then (by a curious perversion of an ancient medical term) called a *polypus*. When it forms a rounded mass in a solid organ it is called a *nodule* or a *tuber*.

When the life-history of the cystic entozoa was unknown, nothing was more natural than that tumours should be imagined to be parasitic like galls on an oak. This notion, however, has proved without foundation. Their life is that of the individual in whom they develop, and at present there is no evidence of their depending on microzoa or microphytes.

Benign and malignant growths.—It was early noticed that whereas some tumours remain for years without affecting the health or causing any inconvenience, others rapidly destroy the patient's life. The distinction between "*innocent*" and "*malignant*" growths is therefore a most natural and obvious one. Further observation brought to light the fact that whereas many of the former kind are like the natural tissues of the body—fat, or cartilage, or bone—many of the latter kind are unlike any healthy tissue. The microscope confirmed this distinction by showing that some soft, white malignant tumours, which from their resemblance to the brain or to marrow had been called *encephaloid* and *medullary*, have an intimate structure which bears no resemblance to normal tissues. Thus a fundamental division was made between *homologous* growths, generally innocent, and *heterologous* growths, generally malignant. It was further supposed that, although there were several varieties of malignant growths, differing in character and appearance, yet that all these belonged to a single disease, which was termed Cancer.

The *word* "cancer," or its equivalent *carcinoma*, was of much earlier origin.* Hitherto its tendency to ulcerate and to eat away the natural structures had been regarded as its fundamental character rather than its anatomical structure. Thus, not only had the venereal "chancre" been confounded with it, but even the "cancrum oris" of children, which we now term noma. Henceforth these were finally separated.

Lebert and the early pathological histologists saw no difficulty in supposing that the tissue of a heterologous growth might differ completely from all the normal tissues of the human body. They made it their aim to discover some particular specific element or "cancer-cell," the presence of which might be an infallible criterion, and solve the frequent difficulties which arose in the anatomical diagnosis of tumours.

In 1847, and the years which followed, the genius of Virchow placed this question in an altogether new light. It had already been shown by Johannes Müller that the structure of every growth, however heterologous in appearance, always corresponded in its ultimate elements with some natural tissue; if not with any of the permanent tissues, at least with some one of those which exist during early embryonic life. Virchow carried the same idea into full detail. As he pointed out, the physiological type of the tailed and irregular cells which had been supposed to characterise cancer is to be found in the epithelium of certain mucous membranes; while the round- or spindle-shaped cells which really make up the substance of many malignant tumours correspond with those which are seen during the development of connective tissue, or (as Billroth has since taught) of muscle or of nerve-tissue. In general, he insisted on the principle that the structure of a tumour in man is always human; so that, for instance, such a tumour might contain hairs but never feathers; whereas, in a bird a tumour might have feathers in it but not hairs. For Virchow, therefore, no growth was *heterologous* in the sense hitherto attached to that term. The distinction, as he drew it, was between tumours resembling in structure the tissues in which they were placed, and those differing from these, though resembling others. Thus, he said that the same growth, which in one situation would be homologous, would in another situation be heterologous. And he further pointed out the necessity of recognising that between certain tissues of the body there naturally exist close relations which are altogether wanting

* Cancer is merely the Latin translation of *καρκίνος*, a crab. This word was applied by the Greek physicians to any eating, gnawing sore. Both *καρκίνος* and *καρκίνωμα* occur in this sense in Hippocrates ('Aph.,' 1257, *et passim*) as well as in later writers. Celsus speaks of diseases, "cum quid intra se ipsum corruptum est, ut in *Cancro*," in close proximity to those which result "cum quid extrinsecus læsit ut in vulneribus" (lib. v, cap. xxvi, 1). A little further on (ibid., xxvi, 31) he says that a cancer ensues from too great inflammation, or too great heat or cold, or too tight binding of a sore, or because the patient is old or of an ill habit of body. "Omnis autem cancer non solum id corrumpit quod occupavit, sed etiam serpit." He goes on to say that the Greek physicians divided cancers into species for which there were no Latin equivalents: as erysipelas, gangrene, &c. He describes (ibid., xxxviii, 2) *καρκίνωμα* as chiefly affecting the upper parts of the body, the nose, ears, lips, and the breasts of women.

Galen admits, however, of *καρκίνος χωρὶς ἑλκώσεως* ('De tumoribus præter naturam,' c. 12), and Paulus Ægineta says, "Cancer tumor est inequalis—interdum sine ulceratione, quem Hippocrates latentem (*κρυπτὸν*) nominavit." This author derived the name from the distended veins of a cancerous breast resembling the legs of a crab (lib. vi, cap. 45), and so Galen; others from the difficulty of getting rid of it ('Expos. vocum medicinalium,' 1564).

Our English word *canker* is an older form of cancer and more generally applied. It is used in the Authorised Version of the New Testament to translate the Greek *γαγγραίνα* (2 Tim. ii, 17).

between them and other tissues, and that such relations have important bearings upon pathology. Thus, all the structures belonging to the connective-tissue series being physiologically related to one another, the presence of bone, or of cartilage, or of fat in fibrous tissue, would not be inconsistent with homology, whereas that of epithelium or of muscle would be.

A still greater advance was made by Virchow in regard to the mode of development of tumours. It had before been generally held that cancer was something deposited from the blood. Chemists had made analyses in the hope of finding in it some peculiar principle for which the name "carcinomatin" had been invented in advance. Its cause was believed to be a "dyscrasia" or ill-mixture of the blood. The fact that active tubercle and cancer are but seldom found in the bodies of the same individuals was thought to support this notion, it being supposed, first, that tubercle is deposited from the blood, and secondly, that the blood could hardly present two different dyscrasiæ at the same time. Yet wounds and injuries undergo repair in exactly the same way in those who are affected with cancer as in other persons: which fact alone should have led to doubt of the validity of this hypothesis.

Virchow, in accordance with his dogma, *omnis cellula e cellulâ*, maintained that the substance of a cancer was developed *in situ* by the growth of the cells and other structures of which it was composed. He was mistaken in the view that they arose by a proliferation of the connective-tissue corpuscles. But this was an insignificant detail in comparison with his rejection of the notion that cancerous and other tumours were "deposits from the blood."

One necessary consequence of Virchow's conception of Cancer was that the so-called cancerous cachexia, instead of preceding the formation of malignant growths within the body, must be a result of their actual presence; and this is quite in accordance with clinical experience. No doubt one of the earliest symptoms of an internal tumour is sometimes the fact that the patient becomes cachectic, that his skin acquires a waxy yellow colour, and that his features look pinched and sharp. But in such cases the tumour really exists long before these indications have appeared. It wears down its victim by pain and distress of mind even if it does not attain a large size or undergo ulceration and hæmorrhage. Lastly, it is certain that some innocent growths, when they cause severe pain and much bleeding, are accompanied by well-marked cachexia; for instance, certain uterine polypi, and even hæmorrhoids and non-malignant tumours of the rectum.

Again, Virchow defined the term *malignancy* far more clearly than previous writers. Hitherto the pain caused by a cancer, and its tendency to destroy life, had been enumerated among the signs that it was malignant. He set these points altogether aside, and insisted that the following four characters are the real indications of malignancy.

1. The *local progress* of a growth, its tendency to increase by extending into the tissues around it. A point on which much stress has since been laid, is the fact that malignant tumours show little or no respect to the natural boundary lines marking off one kind of tissue from another. Thus in a case of cancer of the bladder, the tumour having doubtless started in the mucous membrane, ate its way through the whole substance of the organ, through both layers of the peritoneum, through the muscles, aponeuroses, and other structures of the abdominal wall, until it formed an immense ulcerated cavity, reaching from the pubes to the umbilicus.

There is, however, one exception to this power of overcoming the resist-

ance offered by the different tissues, in the fact that malignant growths seldom penetrate the walls of the larger arteries, whereas they frequently extend into the interior of veins, even into the venæ cavæ. Mr de Morgan remarked that cicatricial structures also sometimes form a barrier to the spread of a cancer, so that when recurrence takes place after an operation the disease creeps along one side of the scar for a considerable distance, without passing over to the other side.

It is a point of some interest that cancers are capable of passing across a serous cavity without previous union between the two surfaces. Of this we had a remarkable instance some years ago. The fundus of the uterus being occupied by a malignant growth, the great omentum hung down into the pelvis, so as to lie in contact with it: these parts were not in the slightest degree adherent to one another, but the lower edge of the omentum contained a cancerous mass. It is not improbable that infection in such cases is the result of active amœboid movements on the part of the cells of the primary tumour; Waldeyer ('Virch. Arch.,' lv) has at any rate detected slow changes of form in cells from a cancer of the breast, and in those of a round-cell sarcoma of the axilla, when placed on a warm stage; but he did not see them move from one spot to another.

2. Its *tendency to return in loco* after having been extirpated by the surgeon. This is one of the facts which used to be urged in favour of the constitutional origin of cancer. According to the modern view, it depends upon the circumstance that a malignant tumour always has outgrowths far beyond the area in which the tissues can be seen by the naked eye to be affected. It is true that surgeons who adopt the new theory are very seldom able to prevent the return of the disease by increasing the size of the mass which they excise; but this, there is little doubt, depends upon the apparently healthy surrounding tissues being more or less widely infiltrated with separate malignant cells. A point which is worthy of notice is that in the case of double organs, like the breasts, the removal of the whole of one gland for a malignant growth is not followed by recurrence in the organ on the opposite side, as might certainly have been expected if the constitutional view were correct. Should such an instance occur, one would probably be right in regarding it as an example of the independent development of a primary cancer in each breast; for this sometimes, though rarely, happens when no operation has been performed.

3. Its *spreading to lymph-glands*. As a rule, the glands first attacked are those which immediately receive the lymphatic vessels from the diseased part. Occasionally it seems to pass over certain peripheral glands, and to begin by affecting others, which lie nearer to the thoracic duct. When remote glands become seats of the growth, the infection has probably been carried, not by lymphatics, but by blood-vessels. As a rule, lymph-spaces round the margins of a tumour take up from it something which is carried into the lymph-stream and deposited in the next gland. There is no difficulty in supposing that this something consists of nuclei, or even of cells from the growth; for Virchow has shown that sometimes an entire lymphatic network—beneath the pulmonary pleura, for example, or the peritoneum—may become filled with such materials, as if it had been artificially injected ('Kr. Geschw.,' p. 52, fig. 4). Whether lymphatic channels exist in the interior of tumours is said by Cohnheim to be still open to question, although Van der Kolk long ago, as he believed, discovered them.

4. Its *becoming generalised*, i. e. *spreading to distant organs and tissues by infection, or, as was formerly said, by "metastasis."*

It is not the mere multiplicity of tumours which indicates that they are malignant. Sebaceous cysts and fatty tumours are sometimes present in great number and yet are perfectly innocent. Perhaps there is no form of malignant disease in which so many nodules are found as in some cases of molluscum fibrosum. But all such innocent multiple tumours have their seat in some particular tissue, and remain limited to that. On the other hand, cancerous growths may appear in almost every tissue of the body at the same time.

Again, in most cases of death from cancer it is easy to recognise some one tumour as the starting-point of all the others. A skilled pathologist recognises this "primary growth," either by its anatomical character or from what he knows of the origin and distribution of the particular kind of tumour. The anatomical difference consists not so much in its greater size as in its being of firmer consistence, from slower growth; or an advanced state of degeneration, or extensive ulceration, may show its earlier date. Locality is another important criterion; for primary cancers, like almost all other diseases, do not arise at random through the body, but are common in certain regions, rare in others, and almost unheard of in most. As a matter of fact it is exceedingly rare to find in the same case two malignant tumours, with equal claims to priority.

Another curious circumstance is that organs and tissues which are especially apt to be the seats of primary growths are seldom affected with secondary or "metastatic" growths of the same kind. For instance, a primary cancer is often developed in one of the breasts; but when secondary growths appear they avoid the opposite breast, nor are they met with in the cervix uteri, another locality from which cancer frequently starts. The most common seats of primary cancer are the lower lip, the tongue and pharynx, the œsophagus, stomach, colon and rectum; the mamma, uterus, penis, and testis; and in these regions secondary cancers are almost unknown. On the other hand, the lymph-glands, liver, lungs, bones, and serous membranes, so frequently attacked by secondary cancer, are very rarely the starting-points of the disease. Nor is this a matter of structure, for the whole epithelial surface of the small intestine is all but exempt from cancer; and some glands, as the parotid, are equally so. With sarcomata no such rule holds.*

In many cases the distribution of secondary nodules or tubera is so limited as clearly to indicate by what channel they were derived from the primary growth. For example, a malignant tumour in the stomach or in the intestine may give rise to secondary nodules in no other organ except the liver, showing that something was carried by the blood of the portal vein which

* An old woman died in Guy's Hospital with cerebral symptoms, and I discovered three tumours in the brain or in its membranes. From their appearance I felt convinced that they must be secondary to a primary growth elsewhere. But I searched every part of the body in vain, until at length I happened to notice that the extreme lower end of the rectum had not been taken out with the rest of the intestine. This, when removed, was found to contain a large ulcer with prominent fungating edges, which evidently was the lesion for which I was looking, although it had given rise to no symptoms during life; even the administration of enemata had failed to lead to its discovery. A microscopic examination of the secondary cerebral tumours afterwards showed that these were "columnar epitheliomata." Now, if I had been able to examine them previously, my task would have been very much more easy, for I should have known almost exactly where to look for the primary affection which gave rise to them.—C. H. F.

served to propagate the disease; or the primary growth being in one of the limbs, the secondary growths may occur only in the lungs, so that the infection obviously took place through the systemic veins and the pulmonary artery. Malignant tumours often penetrate into the interior of veins; there is, therefore, no difficulty in understanding how nuclei, or cells, or even pieces of the growth, may get washed away by the blood-current, and carried to distant parts. Cancerous thrombi form soft colourless masses, parts of which are blended inseparably with the coats of the vessel, while other parts, often much elongated and lobulated, project into its channel, either perfectly smooth on the surface, or coated with a layer of fibrin.* Dr Moxon mentions in the 'Guy's Hospital Reports,' vol. xviii (3rd series), that he had twice seen cancer growing in clots which lay within the cavity of the right ventricle at its apex, brought, no doubt, by the blood of the systemic veins. In 1871 Dr Payne showed to the Pathological Society a heart in which both the right auricular appendix and the apex of the left ventricle contained similar cancerous thrombi projecting from between the muscular trabeculæ. In that instance the infecting agent must have traversed the pulmonary capillaries from one side of the heart to the other.

The distribution of secondary growths is often different from what would have been expected on anatomical grounds. Thus, in a case of epithelioma of the œsophagus, the lungs were found healthy, but a secondary nodule existed in one kidney. Frequently the metastatic formation of cancer is limited to some particular tissue throughout the body, without any obvious relation to the seat of the primary growth. Thus, in a woman with cancer of the breast, almost every bone may become cancerous, while all viscera remain entirely free from the disease.

5. To complete the description of the ways in which malignant growths multiply in the body, a fifth point should perhaps be added to those enumerated by Virchow, namely, the possibility of portions of a tumour becoming *transplanted* when set free upon a mucous surface by ulceration or otherwise. In 1868 Dr Moxon showed to the Pathological Society a specimen in which he thought that an epithelioma of the œsophagus extending into the trachea had in this way infected the lungs: secondary nodules were seated in the interior of the lower lobes, and not beneath the pleura, as is usually the case; they occupied the centres of lobules, and small tubes could be traced up to them. He there mentions that Mr Simon had exhibited specimens in which "cancer germs" had appeared to take root in the bladder after descending the ureter from the kidney. In a case observed by Dr Bristowe, a malignant growth of the interior of the skull had apparently infected the cord low down by fragments which had fallen: and in the abdomen we sometimes find a nodule just opposite to the primary tumour and in contact with it. Nevertheless, all supposed facts of this kind should be cautiously weighed before they are accepted; for there can be no doubt that the particles detached from the face of a malignant growth are, as a rule, dead and already in a state of decay. Cohnheim denies that any authentic case has been recorded of cancer of the uterus in a woman producing the same disease in the penis of her husband. No experimental proof has yet been offered of the possibility of inoculating any kind of tumour from one animal to another. There has sometimes been

* Some time ago I saw an instance in which, the primary growth being in the liver, and the hepatic veins extensively involved, the lower border of one lung contained a whitish-yellow wedge-shaped mass, exactly like an infarctus due to embolism from ordinary thrombosis: Dr Pye-Smith, however, under whose charge the case had been during life, found that it was really a secondary nodule of the tumour.—C. H. F.

a slight apparent commencement of growth at the spot inoculated, but it has always before long undergone reabsorption. Not only has the microscope, aided by modern methods of illumination and staining, entirely failed to discover "germs" or "microbes" in cancers or other infective growths, but the same negative result has been reached by numerous attempted "cultivations," of which the most recent and laborious is that carried out by Messrs Ballance and Shattock ('Path. Trans.,' 1887, p. 412).

Malignant behaviour and cancerous structure.—It must be particularly noticed that the above characters which Virchow laid down as distinguishing malignant from innocent new growths, so far from being peculiar to any special kind of tumour, belong also to other processes, such as inflammation, tubercle, and infective lupus. These exhibit "local progression," and they sometimes pay no more respect to the natural boundaries of the tissues than does cancer itself. The question of their "recurrence after removal" is seldom or never raised. But each of them "spreads to lymphatic glands." Suppuration, at any rate, assuming the form of Pyæmia, undergoes "generalisation" or "metastasis" through the blood. Surely, then, it is more probable that malignancy should belong to several kinds of new growths, perhaps in different degrees, than that it should be a fixed property of one particular species, isolating it from all the rest. Now, that is precisely Virchow's doctrine. Other observers had independently taught the impossibility of drawing an absolute line of distinction between innocent and malignant growths. Sir James Paget described, in 1853, under the name of "*recurrent fibroid*," a growth characterised by an inveterate tendency to return *in situ* after removal, without infecting distant structures. Dr Wilks, in his 'Lectures on Pathology,' published in 1859, made a separate group of "semi-malignant" tumours including, besides the "recurrent fibroid" of soft structures, the "osteo-sarcoma" of bone; and he specially recorded instances in which "myeloid" or "enchondromatous" growths, which were then generally regarded as innocent, appeared metastatically in the lungs. Cancer was left as an independent affection, of which the chief varieties were Scirrhus, or hard cancer; Encephaloid, medullary, or soft cancer; Epithelioma, or horny cancer; Melanosis, or black cancer; Osteoid, or bony cancer; and Colloid, or gelatinous cancer. These forms of cancer were redistributed by Virchow, according to their histological characters. He showed that most instances of "encephaloid cancer," "melanosis," and "osteoid cancer," really belonged to the *connective-tissue* series of growths; and he associated scirrhus with epithelioma, since both forms consist of alveoli containing cells of an *epithelial* type.

Virchow's theoretical views have since been substantially adopted by all pathologists, and the words cancer and carcinoma are now only applied in their strictly histological sense.

Classification.—It is impossible to frame a completely satisfactory classification of tumours. But the following arrangement, which is adapted from that of Lücke, in Pitha and Billroth's 'Handbuch d. Chirurgie,' is probably as good as any. Like all others now in use it is itself a modification of Virchow's.*

* So-called cystic tumours are excluded. If merely dilated cavities containing fluid (retention-cysts), they are no more "tumours" in the modern sense than is a hydrocele. If due to an animal parasite (hydatids) they are not neoplasms, but foreign bodies. If degenerations of solid tumours, their place is with the structure of which they are the outcome.

A. Of the type of connective tissue : mesoblastic
  (α) Following normal or fully developed connective tissues.
    1. *Fibroma*, or fibrous tumour.
    2. *Glioma*, resembling the neuroglia.
    3. *Lipoma*, or fatty tumour.
    4. *Chondroma*, or cartilaginous tumour.
    5. *Osteoma*, or bony tumour.
  (β) Following embryonic connective tissues.
    6. *Myxoma*, resembling the tissue of the umbilical cord.
    7. *Sarcoma*, resembling undifferentiated mesoblastic tissue.
B. Of the type of lymph-glands : mesoblastic.
    8. *Lymphoma*, or lymphadenoma.
C. Of epithelial type : epi- and hypo-blastic.
    9. *Papilloma*, or papillary growth.
    10. *Adenoma*, or glandular tumour.
    11. *Carcinoma*, or cancer.
D. Of the type of higher tissues.
    12. *Myoma*, or muscular tumour.
    13. *Neuroma*, or nervous tumour.
E. Of composite type.
    14. *Angioma*, or vascular tumour.
    15. *Lymphangioma*, or lymphatic tumour.
    16. *Teratoma*, or embryonic tumour.

Many of these forms of tumour have surgical rather than medical interest, and do not need more than mention, but others which affect numerous internal organs will be more conveniently treated here than elsewhere.

1. *Fibroma.*—This is made up of fibrous tissue, which may be either arranged in loose meshes, or felted, sometimes very tightly. In the former case its substance is soft and succulent; in the latter it may be exceedingly hard, so as to creak when cut through.

True fibrous tumours are far from common. The most important are the multiple fibromata of nerve-sheaths, often called *neuroma*. They also occur in tendons and periosteum, particularly in children after rheumatism.

The remarkable little pedunculated fibrous growths, which are sometimes found covering the skin in immense number, will be described with cheloid and other cutaneous tumours, as *fibroma molluscum*. Similar growths of the mucous membrane of the intestine, uterus, or bladder are usually pedunculated, and are called fibrous *polypi*. Fibroma of the breast or ovary is a very rare disease. It is not uncommon for several small fibrous growths to be found in the kidneys, which appear as minute soft white masses, and are apt to be taken for secondary tumours, when there is a growth in some other part. More than once a blunder has only been avoided by the microscope.

1*a*. English writers have, of late, been accustomed to separate, under the name of *Myoma*, a common variety of tumour containing much fibrous tissue, on account of the presence in it of more or less numerous bands of smooth muscle. Most German pathologists now replace these growths, which are seen in the uterus and in the prostate, among the fibromata; and Rindfleisch declares that the opinion that they contain muscular fibres is a mistake. Some small "fibroids," as they are called, certainly have rod-shaped nuclei and other characters of muscle.

There are true myomata (*rhabdomyomata*), or tumours of striated muscle

sometimes found in the kidney and elsewhere. They are of purely pathological interest.

2. The modified connective tissue of the central nervous system, called neuroglia by Virchow, gives rise to a characteristic kind of new growth confined to the brain and (as a rare event) to the cord and the retina, and named *Glioma*. It will be described as the most frequent among "simple" tumours of the brain.

3. *Lipoma.*—This is a tumour consisting of adipose tissue like the subcutaneous fat, but circumscribed, and generally enclosed in a well-marked capsule. They are the largest of all new growths, are often multiple, and common on the surface of the body. When they occur in the interior of the body fatty tumours do not produce symptoms so as to come under medical observation, unless they are so large as to press upon important organs, which is very seldom the case. But Dr Frederick Taylor ('Path. Trans.,' vol. xxvii) met with a case in which a lipoma grew in the post-pharyngeal space of a child, and caused death by suffocation. In the abdomen such growths have occasionally reached an immense size, and have been mistaken for ovarian tumours.

4. *Enchondroma.*—Tumours made up of cartilage were so named by Johannes Müller, although *chondroma* seems to be the more correct form. Histologically they differ widely in different cases; the matrix may be either hyaline or fibrous, and the cells may present various characters. They usually begin in bone, occasionally in the testis or parotid, and are sometimes malignant in their course. As primary growths they scarcely ever come under the notice of the physician. Virchow speaks of multiple chondromata of the lungs, situated chiefly near their roots, and probably bearing some relation to the cartilages of the bronchia; but these, he says, are found accidentally in the *post-mortem* room.

5. *Osteoma.*—This is the technical name for growths which consist of osseous tissue, but it is not often used. For when a tumour projects outwards from a bone it is called an *exostosis*, and when it extends inwards (as into a frontal sinus) it is sometimes called an *endostosis*; and most other bony growths contain soft structures as well, which are regarded as the more essential parts. In medical practice an intracranial exostosis might cause the symptoms of a cerebral tumour. Moreover, as rare exceptions, bony tumours have been found in the brain and in the eye.

There is a very remarkable kind of growth, for which the name *Malignant Osteoid Tumour* seems the most appropriate, and which is of much interest to the physician, because it not infrequently comes under his notice rather than that of the surgeon. By Sir James Paget it was called "Osteoid Cancer." Virchow termed it "Osteoid chondroma," an unfortunate appellation, since (as he himself pointed out) the structure of the non-calcified part of the growth is not that of cartilage, but rather of periosteum. Moreover, as might have been anticipated, great confusion has arisen from its being supposed to be identical with an "ossifying enchondroma," which is a tumour really consisting of cartilage, the deeper and older parts of which have undergone conversion into bone. Wilks and Moxon term this growth "Periosteoma," and define it as representing the varied tissues of ossifying bone.

These malignant osteoid tumours are made up of an exceedingly dense, firm, and tough material, which is of a pale greyish colour, and cannot be teased out. Under the microscope it may appear more or less distinctly fibrous. Sir James Paget describes the fibres as "crisp and stiff," or as

moderately broad, "with uneven thorny edges," and arranged in bundles, "looking like faggots." Embedded in this substance are cells, which are rather small, of round or oval shape, without alveoli. When calcification takes place, earthy salts are deposited in hard granular masses, but in some parts more or less perfectly formed bone may be seen. The calcified growth has a peculiar dull white chalk-like or mortar aspect. It cannot be cut, and must be sawn through, but it may be "rubbed or scraped into a fine dry powder." Malignant osteoid tumours are most frequent in young subjects. Of nineteen cases collected by Paget, five occurred in persons between ten and twenty years old, nine in those who were between twenty and thirty, and none after fifty. They are generally attended with severe pain. Their favourite seat is the lower end of the femur. One in Guy's Hospital affected the humerus close to the shoulder. This kind of growth forms a very large, hard mass, surrounding the whole circumference of the bone, slightly if at all nodulated on the surface, and gradually sinking down to the level of the rest of the shaft. Thus it might seem to be outside the bone, but on section the medullary cavity and the cancellous tissue are found to be completely occupied by the opaque, hard substance above described. When a flat bone is attacked by it, the growth is said by Paget always to project from both surfaces. We had a remarkable case in which the two iliac bones were affected symmetrically, each having a large bossy prominence projecting from both the dorsum and the venter, which might have been felt during life. There may indeed be a large number of such tumours growing from different bones in the same patient, and the clinical aspect of the case may be that of a cerebral tumour or of paraplegia from compression of the cord. Or, again, the symptoms may be thoracic, from an immense mass lying at the root of the lungs, or from numerous nodules scattered in their substance and beneath the pleuræ. The secondary growths in lymph-glands and viscera look like the tumours of the bones themselves. They may be calcified in almost their entire extent, so that only a very little dry, tough, white, fibrous-looking substance remains round their edges. It was this which so surprised the older pathologists, who almost imagined that they had before them cases in which osseous tissue itself possessed the property of malignancy.

6. *Myxoma.*—The true relations of this form of tumour were first recognised by Virchow. Older synonyms for it are "collonema," "sarcoma gelatinosum," and "fibro-cellular tumour" (Paget), but in practice it was probably often confounded with colloid cancer. It consists of a semi-translucent material, sometimes so soft as to quiver like a jelly, of a bluish or yellowish tint, and emitting a sticky fluid when squeezed or scraped. This comes from the intercellular stroma, and owes its viscidity to the presence of mucin. The addition of acetic acid to a thin slice of the growth renders it white and opaque from precipitation of the mucin.

The cells are generally scattered at considerable intervals. They may be round, but they are often stellate, with long processes ramifying in the stroma. Virchow pointed out that this structure is identical with that of the gelatinous tissue, which in earlier fœtal life occupies the place of the subcutaneous fat, which at birth is found in the umbilical cord, and which constitutes the vitreous body of the eye. Myxomata are seen chiefly by the surgeon, but the physician may occasionally meet with them in various situations, even in the brain. Sometimes they are found in large numbers upon the nerve-trunks, constituting a part of the tumours which were formerly

incorrectly grouped together under the name of *neuromata*. Myxo-lipoma and myxo-chondroma are sometimes met with. Some polypi of mucous membranes are fibro-myxomatous in structure, and so according to Virchow are "hydatid moles" of the uterus.

7. *Sarcoma.*—Virchow referred to the *connective-tissue* series of growths as certain tumours which present a high degree of malignancy, especially those known as "encephaloid" and "melanotic" cancers. He grouped them with other tumours of innocent character, or which at most exhibit a tendency to return *in loco* after extirpation, and he adopted for them all the name of sarcoma. His views with regard to them have since been universally accepted; in this country the more readily because no confusion could arise. For the word Sarcoma, although it dates back to Galen,* and had been employed by many subsequent writers down to the time of Abernethy, had fortunately fallen into complete disuse except in the compound form of osteo-sarcoma.

A point on which Virchow laid some stress as distinguishing sarcomata from growths of which the cells were epithelial, was the absence in the latter of any intercellular substance or matrix. This still holds good in so far that, where the cells of a tumour are embedded in a structureless or granular material, the conclusion may be drawn that they are not epithelial; but the converse is not universally true, for the elements of certain spindle-cell and other sarcomata are often tightly packed together without anything between them.

The cells of a sarcoma may be of three kinds:

a. Round-cells.—These vary in character in different cases. Sometimes they are undistinguishable from leucocytes. Sometimes they are much larger, and they are then often exceedingly delicate, so that the addition of water to a microscopical specimen may cause the disappearance of all but the nuclei, which then seem to be free.

b. Spindle-cells.—These are the growths which by French writers had been called *fibro-plastic*, and which had in England been recognised by Paget and others as characterising the class of tumours which he termed "Recurrent Fibroid." They present many differences of size and appearance, but they all agree in having an elongated shape, tapering gradually into a point at each end, or having their ends prolonged as delicate sinuous fibres. Their nuclei are always elliptical, and sometimes narrow and oat-shaped. They are commonly "fasciculated," *i. e.* arranged side by side in bundles.

c. Giant-cells.—Under this name are now described certain bodies, which, however, are rather irregular masses of protoplasm than cells, and which contain round or oval nuclei to the number of ten, twenty, thirty, or even more. From similar elements being found in the medulla of bones, especially during fœtal life, as Kölliker and Robin pointed out, they were until recently termed "myeloid cells," or by French writers *myéloplaxes*. Indeed, the growths in which they occur, and which are comparatively infrequent, were by Paget, Wilks, and others described as a special kind of tumour. Virchow, however, insisted on the fact that such growths always contain spindle-cells as well, and that therefore their true place is among the sarcomata.

But different kinds of cells by no means constitute the whole of the formed elements of a sarcoma. It also contains blood-vessels, which are sometimes so large and receive so abundant a supply of arterial blood, that

* Σάρκωμα ἐστὶ σαρκὸς ἐν τοῖς μυκτῆρσι παρὰ φύσιν αὔξησις, ἐστὶ δὲ σάρκωμά τι καὶ ὁ πολύπους.—'Galeni de Deform. medendis.'

it may pulsate, so as to be mistaken for an aneurysm. The walls of the smaller branches of these vessels are usually themselves of embryonic character, consisting of spindle-cells applied to one another in such a way as to enclose a blood-channel between them. It is, therefore, not surprising that they are apt to allow blood to escape into the substance of the growth, where it may coagulate, so that on section the mass looks like a mere clot. Such tumours increase in size with extraordinary rapidity; and they were formerly known as *fungus hæmatodes*, a name now almost forgotten. In other instances, there are so few cells between the vessels that there may be the greatest difficulty in recognising the presence of any new growth.*

Again, instead of being embedded in a merely granular material, the cells of a sarcoma may be supported by formed stroma, consisting of connective tissue. This, however, is hardly to be regarded as equivalent to the ordinary intercellular substance, for the fibres have no doubt been developed out of a corresponding number of the cells, and have taken their place. The growth is in fact a mixed one, a *fibro-sarcoma*. Sometimes, as Billroth pointed out, there is a regular alveolar structure, like that which characterises carcinoma; the cells are, however, smaller and the stroma less developed. Of late years, since it has been thought that cancers proper can arise only where there is epithelium, "alveolar sarcomata" have acquired importance, from enabling pathologists to account for apparent exceptions to this rule.

Still greater complexity is caused by the combination, in the same tumour, of a variety of structures belonging to the connective-tissue series, such as cartilage, mucous tissue, bone or fat. Perhaps the occurrence of certain rare cases in which a growth, ordinarily innocent, sets up secondary tumours in distant organs may be explained by the presence in it of more or less numerous embryonic cells, the diffusion of which by the blood-stream causes the infection. According to this view all such tumours are "mixed," and should be designated accordingly. In a case at Guy's Hospital fibromata of the uterus led to the formation in the lungs of similar growths in which the appearances regarded by many pathologists as indicative of unstriped muscular fibres were as conspicuous as in the uterine tumours themselves. And in another case, that of an infant fifteen months old at the time of death, there were in the liver, secondary to a mixed sarcoma of the neck, a number of dense flat button-like nodules, which consisted almost entirely of well-developed fibrous tissue, although at the margins some spindle-cell elements were with a little difficulty discovered.

Another circumstance which greatly modifies the appearance of sarcomatous growths is the occurrence in them of degenerative changes, of which caseation is the chief.

Can we, without having recourse to the microscope, distinguish the

* In 1877, I made an autopsy in the case of a lad, aged fifteen, who had been under Mr Cooper Forster's care for a fracture of the femur, which seemed clearly to have been caused by external violence. Repair did not take place, an incision led merely to the escape of blood; and amputation was followed by the death of the patient. I found the injured bones and muscles soaked in blood, and at first I had no suspicion of there being any tumour elements. But presently I noticed that the blood-stained appearance of the muscles was limited definitely by convex margins; and the microscope showed masses of delicate spindle-cell tissue in them. In the lungs there were five or six scattered secondary nodules, the size of marbles, and reddish in colour, projecting above the level of the pleural surface. These, however, felt quite soft; and when cut into, each of them collapsed, leaving a cavity surrounded only by a very narrow margin of indefinite-looking tissue. For further details of this case see the 'Guy's Hospital Reports' for 1880, p. 17.—C. H. F.

great toe. He complained of pains in his right arm, in both shoulders, in the loins, and (especially during defæcation) in the lower part of the spine. He also suffered severely from headache. The urine was at one period albuminous, and the case was therefore regarded as one of Bright's disease of gouty origin. Subsequently the urine became normal, and some of those who saw the patient at that time suspected that he was exaggerating his symptoms. However, he grew more and more wasted and bloodless, and his pains became fixed in the iliac fossæ, especially on the right side. The most careful search was made for tumours, which it seemed could hardly escape detection in so emaciated a subject. A few weeks before death hæmaturia occurred, and this of course led to the suspicion of primary malignant disease of the kidney. At last he became unconscious, with rigid flexion of the right arm, and in this state he died. The autopsy showed that sarcomatous growths had occurred to an enormous extent, but that there was nowhere any tumour discoverable by manipulation. In each iliac fossa a layer of sarcomatous tissue was spread out beneath the periosteum, and there was a large quantity diffused over the surface and in the interior of many other bones. One tumour, which was removed, and sawn vertically through, had in its cancellous tissue many rounded masses as large as walnuts. On the under surface of the dura mater there were a number of button-like nodules indenting the brain. One kidney had two small tumours affecting the mucous lining of its pelvis. The growth consisted of large cells of the most irregular form embedded in a fibrous matrix.

Another case is that of a boy, aged sixteen, who came under the writer's observation when clinical clerk to Dr Owen Rees in 1854. He said that he had been strong and robust until eleven weeks before his admission, when he began to suffer from pain, at first in the loins, and afterwards in the shoulders and limbs. There was great tenderness of the whole surface of the body. He had also experienced a sensation of tingling in the area of distribution of the ulnar nerve to each hand. He was a very delicate-looking lad, with a clear complexion, a pink flush on each cheek, a moist skin, a white tongue, and a pulse of 144. The first diagnosis was of subacute rheumatism; subsequently of chronic inflammation of the spinal membranes. He lay for about two months, during which time he became emaciated to the most extreme degree. Towards the last, masses of enlarged glands could be felt through the walls of his contracted abdomen. He continued to suffer excruciating pain on the slightest movement, and there was exquisite tenderness of the skin. One day he became insensible, and had a convulsive attack, after which he lived only three hours. A large mass of medullary sarcoma was found in front of the spine, eroding the vertebræ, and involving the nerves as they emerged from the spinal canal.

Sometimes the growth of multiple sarcomata leads to a still more rapidly fatal illness. In vol. xxv of the 'Guy's Hospital Reports' are recorded certain cases which were attended with purpura and other hæmorrhages from mucous surfaces. One of the most curious is that of a man, aged twenty-five, who was admitted in 1879 for what was supposed to be an attack of rheumatism. He said that on Whit Monday, June 2nd, he had got wet through; and from that time up to his admission, two months later, he had complained of pains in the left shoulder, in the chest, and in the hips. He had been confined to bed for nine days with profuse sweating; the temperature varied from 102° to 102·3°. The skin had an unpleasant sour smell,

and a systolic apex murmur was detected on one occasion when he sat up. He went on well for twelve days, when a purpuric rash came out on the chest and the abdomen, hæmaturia occurred, and his eyelids and his scrotum became greatly swollen. Five days later, on August 14th, he died. At the autopsy the scattered spots of purpura still remained visible. Some of them were flat, but others were slightly raised and indurated, and a few had a central pale elevation with a narrow ring of purple discolouration around it. These proved to consist of small round or irregular cells infiltrating the little lobules of subcutaneous fat. In the kidneys there were several white or pinkish sarcomatous nodules. In the cæcum and adjacent part of the ileum there was what appeared to be the primary growth, a homogeneous-looking yellow mass, of considerable thickness, involving all the intestinal coats.

Another case occurred in a patient, aged thirty-eight, under Dr Moxon in 1877. Up to five weeks before admission he had always, he said, been a strong man. He then "caught cold from being exposed to draughts." After this he suffered from pains in the back, legs, arms, and chest, chiefly in the joints, and flying from one joint to another. Five days before he came into hospital he was attacked with severe pain in the back, hæmaturia set in, and purpuric spots came out on the neck, the groins, and the legs. Afterwards he had epistaxis, his gums became sore, and bled. His temperature had been taken before admission, and was found to range from 100° upwards. On admission he was much blanched and extremely weak, with no perceptible pulse. The nose began to bleed almost immediately, and on the following morning he died. The kidneys were found to contain a large number of white tumours, and there was in the right vesicula seminalis a firm growth, to which they were apparently secondary.

A third case was that of a man, aged twenty-eight, admitted under the care of Dr Wilks in 1872. He said that for some weeks he had suffered from headache and neuralgia, that his teeth had been loose and painful, and that his gums had been spongy and had bled. For ten days he had been suffering with severe pains in the elbows, the knees, and the shoulders, but these seemed to be diminishing in intensity. He was an anæmic man, with a brown tongue, foul breath, and teeth and gums caked with dried blood. His pulse was 128, his temperature 100·2°, his respirations 28. His gums and his nose continued to bleed, and eight days after his admission purpuric spots appeared on the abdomen. On the following day he died. A whitish firm growth was found in the anterior mediastinum, probably affecting the thymus; and there was a large quantity of a similar material in the subserous tissue of the peritoneum and in the mesentery.

A fourth case, somewhat like the others, occurred in February, 1876. The patient, a bank clerk, aged twenty-five, said that he had got very cold about a fortnight before Christmas, 1875; for three days he was chilled through, and he was never well afterwards. His temperature was 101°. His mouth and his tongue were stained with blood, his gums were slightly spongy, and he had purpuric spots on the legs. It appeared that he was not in the habit of eating any vegetables, and the disease was supposed to be scorbutus. But he rapidly grew extremely anæmic and feeble, hæmorrhage from the bowels set in, the lymph-glands in various regions of the body became enormously large, and at the end of a few months he died. There was no autopsy.

Different views may be taken as to the relation between the symptoms which presented themselves in these various cases, and the underlying

other hand, few German pathologists employ it at all. So that its true position in the nomenclature of disease is that of being a French equivalent for the German term lymphoma. Several English writers apply it in a more limited sense, to correspond with what will be hereafter described as "Hodgkin's disease." In that morbid condition there are, indeed, growths which spring up in immense numbers, and sometimes with extreme rapidity, not only in the lymphatic glands and the spleen, but in almost every organ and tissue; and they may possess at least the first of Virchow's characters of malignancy, spreading from one part to another without regard to the natural boundary lines between them. It is impossible to reserve for them the term lymphadenoma, or to describe them under any one pathological designation. For their histological characters vary widely in different instances, so that we must regard "Hodgkin's disease" as a clinical name for a group of cases in which the same organs are affected, and of which the symptoms and course are similar, but not as anatomically denoting any one special kind of tumour.

Another term, "lymphosarcoma," also needs explanation. Like lymphadenoma, it has been employed in somewhat different senses by different writers. Some seem to apply it to any sarcomatous growth having its starting-point in lymphatic glands; they forget that the seat of a sarcoma is in itself a matter of indifference, and certainly does not require to be marked by any special name. On the other hand, Virchow is disposed to designate as lymphosarcomata all lymphomatous tumours of any size, of which the elements show no tendency to caseate, and which undergo progressive and sometimes very rapid enlargement; he would include under this head most instances of Hodgkin's disease, and all the lymphomatous tumours of the mediastinum. But it is certain that many of the cases in question, even where a large number of organs are involved, exhibit no histological characters other than those of a pure lymphoma. The only logical course seems to be to reserve the name of lymphosarcoma for such growths as appear to be transitional between a lymphoma and a sarcoma. Lymphoma will then denote a tumour composed of lymphatic, adenoid, or cytogenic tissue.

New growths of epithelial type.—As already remarked, we owe to Virchow the important doctrine that the "cancer-cell," which was believed by histologists to be heterologous, *i. e.* unlike any of the elements of the healthy body, is, after all, identical with the cells of epithelium. He explicitly pointed out this fact in a paper in the first volume of his 'Archiv,' published in 1847; and at the same time he indicated the region in which the most perfect representatives of cancer-cells are to be found, namely, upon the mucous surface of the ureters and of the bladder, especially in infants. He also made a striking comparison between the alveolar structure of a cancer and that of the lung in a case of lobular pneumonia, where the pulmonary vesicles are filled with corpuscular exudation which is just turning into pus. It is a remarkable fact that, at a much later date, pathologists, still ignorant of his teaching, actually made the diagnosis of cancer in the urinary passages or in the lungs, on microscopical evidence alone, in cases where no disease was present.

It is much to be regretted that Virchow did not carry out his usual method of nomenclature, and stamp with his authority the practice of applying the term "epithelioma" to all tumours of epithelial type. Unfortunately,

it was already in use, as a designation for a very limited group of cancers, characterised, however, not by the presence of ordinary columnar or spheroidal epithelium, but by that of horny epidermic cells. Hereafter, perhaps, the term "Epithelioma" will universally be employed, in the wider sense which seems naturally to belong to it.

Epithelial growths, however, are not all of them included under cancers. There are certain innocent forms which bear the names *papilloma* and *adenoma*. These bear the same relation to one another which an intestinal villus does to a Lieberkühn's tubule. The former consists of a solid protrusion outwards of mucous membrane or of skin, upon which epithelial cells are arranged; the latter is a hollow inversion of mucous membrane or of skin, with an epithelial lining.

9. *Papilloma.*—Of this we have examples in common cutaneous warts, and in the horny growths which are sometimes seen upon the face, neck, or chest. Another common variety occurs as warts on the genital organs, and a fourth as condylomata and mucous patches; these will be mentioned among diseases of the skin. Yet another form is sometimes met with in the larynx, especially at an early period of life. Lastly, there is an affection to which the vesical mucous membrane is liable, and which is known as "villous tumour" of the bladder, or sometimes (on account of the alarming and dangerous symptoms to which it gives rise) as "villous cancer." It consists in the formation of one or more tufts of long, soft, delicate-branched filaments, each containing a wide vascular loop, and covered with a series of layers of large epithelial cells. This kind of new growth does not spread to lymph-glands, nor produce metastatic nodules in distant parts. Billroth still continues to place it among the carcinomata, on the ground that masses of epithelial cells lie in meshes at the basis of the villi; and in some cases the resemblance to the structure of a cancer is certainly very close.

10. *Adenoma.*—Of this form of tumour (which resembles true gland tissue, not that of a lymph-gland) an instance may be found in molluscum contagiosum. Other examples also are met with, corresponding some with the sebaceous, some with the sudoriparous glands. Upon mucous membranes the most common variety is one which constitutes a large number of so-called "polypi," growing from the surface of the intestine, of the cervix uteri, or of the nasal fossa. In the female breast adenoma or adenocele, the "chronic mammary tumour" of Sir Astley Cooper, very frequently occurs.

11. *Carcinoma.*—The structure of the two kinds of new growth last described is by no means always identical with that of the part in which they arise; thus a nodule of molluscum differs considerably from the healthy skin in its histology, and a villous tumour of the bladder from the vesical mucous membrane. So that it is impossible to maintain in its integrity the dictum of Waldeyer, which is cited by Lücke with approval, that the carcinomata can be absolutely distinguished from other epithelial growths by their being "atypical." Probably the fact is that, as in so many other departments of pathology, no positive line of demarcation exists. The carcinomata, indeed, may be said to combine in many cases the distinctive features of a papilloma with those of an adenoma, in so far that they consist partly of outgrowths covered with epithelial cells, partly of inversions lined with them. Thus a cancer of the skin often begins in a growth resembling a wart; many cancers of the stomach, of the intestine, and of the gall-bladder present abundant villous processes; and in the os uteri, nothing is more

common than for a cancer to begin as what is termed a "cauliflower growth." The glandular type is shown in the characteristic alveolar and epithelial structure of cancer.

a. Ordinary carcinoma (*glandular cancer, malignant adenoma*) presents a great many varieties of structure according to its exact seat. But it is always made up of oval or rounded alveoli, which contain cells like those of epithelium. The walls of the alveoli usually consist of fibrous tissue, and they are more or less abundantly supplied with blood-vessels. In very soft, rapidly growing cancers, however, the interalveolar stroma may be composed of spindle-cells; or, in other words, its tissue may be sarcomatous. Otherwise the softness or hardness of a carcinoma depends chiefly upon the proportion between the amount of stroma and the size of the alveoli. In many instances the substance of the growth is as easy to break down as that of a healthy spleen, or even of a spleen from a case of fever; and then one finds that the alveoli are large and that their walls are made up mainly of blood-vessels, and have but little fibrous tissue in them. Sometimes it is so hard as to be spoken of as "stony;" the microscope then shows that it consists almost entirely of interlacing dense white bands, the alveoli being very small, and perhaps so few in number that their presence may easily be overlooked. It is to such growths that the old name of "scirrhus" is still applied. They are commonly very slow in their course; and they contract and shrink so much that their general appearance is often that of a cicatricial relic, rather than of a tumour; and if they occupy the wall of a canal (such as the intestine or the common bile-duct) they greatly narrow it.

As to the extent to which the alveolar walls and stroma of a simple carcinoma are a new formation, there is still some uncertainty; and perhaps different cases differ in this respect. The analogy of keratoid carcinoma, which will be described further on, suggests that they may be in great part made up of pre-existing tissue-elements, modified in their arrangement by the pressure of the masses of epithelial cells which are in contact with them on all sides. On the other hand, it is certain that in growing cancers the alveolar walls generally contain numerous leucocytes, from which a new fibrous tissue may well be supposed to be developed. As Waldeyer remarks, when a carcinoma spreads in the interior of a thrombus within the channel of a vein, its alveoli can be nothing else than entirely new formations. In cases of this kind, however, the alveoli are sometimes ill marked.

In thin sections of a carcinoma the alveoli look like closed spaces, but in reality they freely communicate with one another in different planes. Thus, when one gently squeezes the cut surface of such a growth, or when it is scraped with a knife, the cell-masses, with more or less of an albuminous fluid, escape readily, forming what has long been known as the "milky" or "cream-like" *cancer-juice*, or appearing as a soft, curdy, solid substance. The cell-masses themselves—the "*cancer-bodies*," as Waldeyer proposed to call them—may sometimes be withdrawn in continuity from two or more alveoli, so as to have a branching or reticulated appearance. The cells of which they are made up present every variety of shape, "polymorphism" being indeed one of their characters. Each has commonly a large, sharply defined, round or oval nucleus, and sometimes two or even more. The protoplasm is abundant, sometimes clear but often granular.

b. Keratoid carcinoma.—This is the form of growth which is commonly known in England by the inappropriate name of "Epithelioma," originally

given to it by Hannover, of Copenhagen, in 1852. Many French writers and the late Dr Hughes Bennett, following Lebert, called it "cancroid." Its characteristic is the fact that some of its cells undergo a chemical change identical with that which constitutes *cornifaction* in the superficial layers of the epidermis. The horny cells are situated near the centre of the "cancer-bodies" in which they occur. They become fixed together, and the pressure to which they are subjected moulds them into globular masses, more or less laminated in structure, but often having a transparent centre, which looks like a single large cell. These bodies were called by Lebert "epidermic globes." In this country they are known as "birds' nests." It must be clearly understood that in themselves they afford no proof whatever of the presence of a malignant new growth. On the contrary, they may be found under various circumstances, as, for example (according to Thiersch), "in lupus, in the hyperæmic borders of cicatrices, in sebaceous tumours, and in the epithelial covering of the gums." Their real importance lies in the fact that when they are seen in a new growth they show it to be not merely a carcinoma, but one which has its origin either in the skin or in some mucous membrane having a squamous, laminated epithelium. This form of cancer is exceedingly frequent about the orifices of the body, especially the lips, the anus, and the vulva. The mucous membranes upon which it may occur are those of the mouth, tongue, pharynx, larynx, and œsophagus, the lower part of the rectum, the urethra and bladder, the vagina and os uteri. In many of these situations, however, it is common to meet with growths which, although the presence of horny globes justifies the title of keratoid carcinomata, yet contain the globes in small numbers, and in their general appearance and structure approximate very closely to the ordinary form of cancer. Such transitional varieties are met with in the bladder, and they are very common in the cervix uteri. In the œsophagus they appear to increase in frequency from the pharynx downwards, until at the cardiac orifice of the stomach a point is reached at which the liability to cornifaction in the cancer-bodies ceases altogether. Another proof of the close relation between the two forms of cancer is sometimes afforded by an examination of the structure of the secondary nodules in distant parts from a case in which the primary growth is keratoid. In some instances a nodule in the kidney or in the lung will present horny laminated globes (birds'-nest bodies) as well formed as those in the original seat of disease in the tongue or œsophagus. In a recent case of keratoid cancer of the lip in which the cervical glands contained typical globes, some large secondary masses in the liver, which were softening centrally into cavities, had more the structure of a simple carcinoma, the indications of cornifaction of the cells being slight and imperfect. The keratoid form of cancer is, however, much more apt to infect the lymph-glands which correspond with its primary seat than to be carried to distant parts by the blood-stream.

In the more characteristic cases of keratoid carcinoma, the material which can be scraped or squeezed from the cut surface of the growth is firm and granular looking, like the secretion of a sebaceous gland. It often comes out in the form of long worm-like masses.

Histologically, keratoid carcinoma differs from common cancer in some other respects as well as in containing the "globes" or "birds' nests." Not infrequently some of the cells have prickle-edges. Another peculiarity is that the "cancer-bodies" are much more plainly seen to form continuous bud-like branching processes which grow more or less vertically downwards

from the surface, penetrate the deeper structures and push them aside. Indeed, in its typical forms keratoid carcinoma may be said to present no definite alveoli. The substance that intervenes between the different cancer-bodies was all of it pre-existent, and it has undergone little change except that it is commonly infiltrated with leucocytes.

It seems now to have been clearly proved that the so-called "*Rodent ulcer*," which occurs chiefly on the face of persons advanced in life, and which is characterised clinically by its very slow course, is only a variety of keratoid carcinoma. In all probability the same may also be said of the affection termed "*Cylindroma*" by Billroth, in which certain peculiar hyaline bodies are found.

c. Columnar carcinoma.—In 1852 Bidder, of Dorpat, described in 'Müller's Archiv' a case in which the cells of a soft cancer of the pylorus were identical with those of "columnar" or "cylinder epithelium." Many other instances of the same kind have since been recorded under the title "cylinder" or "columnar epithelioma." The area of distribution of this form of tumour, as a primary growth, includes the stomach and intestines, from the cardia downwards to within a short distance of the anus, the biliary passages, and gall-bladder, and (according to Cornil and Ranvier) the nasal fossæ, the upper part of the uterine cavity, and perhaps the ovaries. Secondary nodules may occur almost anywhere: we have found them in the liver and the brain, and other observers record them in the lungs and in bones. The appearance of a primary columnar carcinoma is commonly that of an irregular shallow ulcer with a soft, raised, slightly projecting border. It may yield an abundant juice, full of the columnar cells, which are often still coherent sideways. A thin section generally shows that they are regularly arranged around the borders of long-branching channels or alveoli. But, as Cornil and Ranvier admit, some of them may be polymorphous. Indeed there are clear transitions between this and other forms of cancer, not only among different primary growths, but also in comparing primary and secondary growths from the same case, when the latter sometimes approximate to the common type of carcinoma.

Histogenesis of carcinoma.—That epithelium alone can produce epithelium is almost established by what is known of the healing of wounds and ulcers from their margins, and by the success of Reverdin's practice of transplanting cuticle. So also primary tumours of epithelial type arise only in those structures which contain epithelial elements. This fact is perhaps not quite without exceptions. German writers still cite a case of Virchow's, recorded in 1850, in which the tibia is said to have been affected by a primary "cancroid," the skin being healthy, and Otto Weber is quoted as having in 1859 related a case in which there was a similar lesion of the lower jaw. One may, however, hesitate as to the value of observations made at a time when their theoretical significance could hardly have been appreciated. Far more important is the fact that Waldeyer and other recent investigators have failed to meet with a single instance of the same kind. It would, indeed, be easy to account for the occasional occurrence of exceptions to the rule. Apart from the difficulty of discovering in all cases the growth which is really primary, it might be argued that it is possible for a lesion starting from the skin to extend downwards and to spread into the deeper structures, so as to appear to have begun in them. Paget, for instance, speaks of having "seen two examples of primary epithelial cancer in lympathic glands;" one was in a sweep, whose

groin contained a large mass, notwithstanding that the penis and the scrotum appeared to be unaffected. But it may be doubted whether the microscope might not have thrown fresh light upon the matter. Thiersch records a case in which a nodule seemed for a time to be subcutaneous, but really had its origin in the sweat-glands. Some carcinomata seem definitely to arise from the cells belonging to the glands of the skin or mucous membrane, rather than from those which cover the surface. Further, it is conceivable, as was suggested by Remak in 1854, that a fragment of germinal epithelium, embedded in other tissues from fœtal life, may afterwards develop into a cancerous tumour, instead of forming an innocent dermoid cyst. According to Thiersch it is no uncommon thing for cancer to arise in the wall of such a cyst after it has existed for many years; and Waldeyer cites an instance in which a similar change occurred in a congenital sacral tumour.

Even recently, however, some pathologists have maintained that although epithelial cells are formed only in contact with pre-existing epithelium they yet arise out of cells which are not themselves epithelial. Klebs speaks of an "epithelial infection," by which, for example, in a healing ulcer the rete mucosum of the skin at its margin is supposed to convert the cells of the adjacent granulations into epithelial cells. But, as Waldeyer remarks, there are striking instances in which a cancer fails to impress its own characters even upon epithelium with which it happens to come into relation. Thus, although the secreting cells of the liver are directly concerned in the development of some of the primary carcinomata of that organ, they are pushed aside by secondary nodules, and take no part in their formation.

In 1867 Köster propounded the view that the cells of cancerous growths in the skin are formed from the endothelia of lymph-channels. This, however, has met with no support; Waldeyer says that he has repeatedly seen cancer-bodies lying in immediate contact with perfectly unaltered endothelium, and although he admits that they often penetrate into lymph-channels and occupy them, he maintains that it is far from being always the case. On the whole, if we are not to cling to the notion that the epithelial cells are solely devloped by germination or fission from pre-existing epithelium, it would seem to be more easy to accept the view that they arise out of ordinary leucocytes. The tissues in immediate contact with a primary cancer are very commonly infiltrated with leucocytes; and, if they do not contribute to the new growth, their presence requires some other explanation. It is more likely that they are the results of a reactive or inflammatory process, of which a more intense degree is seen as ulceration of the growth. Waldeyer observed that the cancer-cells themselves are altogether passive when ulceration occurs; they break down and escape with the discharge. But there can be little doubt that the putrid and offensive character of the ichor which exudes from an open cancer is due to the extension inwards of a septic contagium along the epithelial columns and through the alveoli, which, as we have seen, communicate with one another.

Caseous decay.—Carcinomata are liable to certain retrograde changes beginning within their substance. Like sarcomata and almost every other kind of hard growth, they are apt to undergo "caseation." Whether this is altogether spontaneous—an indication that the cancer-bodies have reached their natural term of life—or whether it is due to interruption of blood-supply, has not, apparently, been ascertained. It often affects all but the narrowest possible growing margin of a tumour, especially of a

secondary nodule. And not uncommonly, where a caseating tumour is seated in the interior of a solid organ, such as the liver, its centre softens down so as to produce a cavity filled with a straw-coloured albuminous liquid.

Colloid carcinoma.—The most remarkable transformation of cancers, and one which never occurs in sarcomata, is that known as "*colloid.*" Chemically it resembles the substance of the thyroid body when enlarged. Colloid material differs from mucus in not being precipitated or rendered opaque by acetic acid, and also in containing sulphur. Cancers which undergo this change sometimes occur in the breast, but scarcely anywhere else except within the abdomen. At the pylorus one can sometimes trace very clearly the gradual conversion of a simple carcinoma into colloid. Until the nature of the colloid degeneration was understood by pathologists, there was no greater puzzle. The abdomen was sometimes found filled with enormous gelatinous masses, in which the microscope showed no definite structure, but which yet penetrated organs and destroyed them in such a way as clearly to show that it possessed malignant characters. In 1847, Virchow imagined it might be a persistent condition of the gelatinous exudation out of which, at that time, all cancers were supposed to develop. Long afterwards it was described as a separate variety of carcinoma; but of late the doctrine has met with general acceptance that it is not a primary species of tumour, but the result of a peculiar degenerative process. There can be no doubt, however, that much new colloid material is in a growth which is undergoing this change, for its alveoli have so enormously increased in size that they are often visible to the naked eye. Indeed, formerly, when the alveolar structure of all carcinomata was not known, the terms "alveolar," "cystic," or "reticulated" cancer were often applied to what we now call colloid.

The epithelial cells become swollen out into glistening, structureless globes; and it is only towards the centre of some of the alveoli that a few unaltered cells may still remain visible. Immense masses of cancer, having undergone this degeneration, sometimes fill the abdominal cavity, lying in great part loose and unattached to the serous membrane. In such cases it may be only after careful search that one discovers any portion of the growth in an unaltered state. The primary growth is usually found in the stomach or intestine. Secondary tumours, even when apparently recent, reproduce the colloid structure, and this fact renders it doubtful whether this structure is really a mere degeneration.

Ætiology.—There is no doubt that malignant growths are hereditary more frequently than others. The experience of Sir James Paget is very striking; in his hospital days he found that the proportion of cases in which a family tendency could be traced was one in six; subsequently in private practice, he made it one in four, and still more recently it has become one in three. It is true that these results might perhaps lose some of their significance if we were to inquire as to the proportion of healthy persons, chosen at random, who would be found to have had one or more relations affected with cancer, supposing their family history to be scrutinised with sufficient care. Some of the cases recorded by Paget and by others are far too striking to be set down as mere coincidences. Thus a lady, who died with cancer of the stomach, had seven children and about thirty grandchildren who grew up. Some of them were still living; but a daughter had already died with cancer of the stomach, two granddaughters with

cancer of the uterus, a granddaughter with cancer of the breast, a grandson with cancer in the bladder, a grandson with cancer in the rectum, and a grandson with cancer of the axillary lymph-glands.

A point of considerable importance is that where the disease is transmitted by inheritance it often appears in the descendants at a much earlier age than in the first patient. Thus, a young lady of twenty-four died of "epithelial cancer" of the pharynx; her mother had been attacked by cancer when between forty and fifty years old, her grandfather between sixty and seventy, a great-aunt at about forty, her great-grandmother at eighty or older. A schoolfellow of the writer died of cancer of the rectum before he was forty years of age; his father and his grandfather were believed to have also suffered from cancer, but at advanced periods of life.

In the 'St Bartholomew's Hospital Reports' for 1866, Mr Morrant Baker analysed 103 of Paget's cases, and carefully investigated the question whether the appearance of cancer in successive members of the same family could be attributed to the mere propagation of a *local* defect, or (in other words) of a tendency of some one organ to a special morbid change. But he found that it was hardly more common for the disease to occur at the same spot in two members of the same family, than for its seat to be different. Hence it would appear that we cannot explain the inheritance of cancer as a case of inheritance of the structure of particular organs.

A scarcely less important question is whether heredity is limited to cancer or applies to all neoplasms. On this point Cohnheim states that sometimes a mother suffers from adenoma of the breast, and her daughter afterwards from cancer of the same organ; and among Paget's observations there are several in which it seems clear that carcinoma occurred in one member of a family and sarcoma in another. So again, Sir William Jenner mentions the case of a man who had cancer of the tongue, and whose child, twenty-two years before, had died at the age of two or three years with disseminated malignant growths, which one may presume to have been sarcomata. In truth, there are grounds for stretching to the widest possible extent our conception of the inheritance of a tendency to develop tumours. In the course of the discussion of the Pathological Society in 1874, Mr Hutchinson remarked that persons who had common warts in large numbers generally knew of relatives affected with cancer. And Dr Goodhart shared with the writer the impression that, in the deadhouse at Guy's Hospital, it was very common to find all kinds of innocent tumours in the bodies of those who had died of malignant growths. Moreover, Paget has insisted on the frequency with which liability to sebaceous cysts, or to certain multiple osseous tumours, is transmitted by inheritance.

Thus, it appears that the hereditary propagation of cancer is only part of the widely-spread occurrence of new growths of various kinds in certain families.

Clinical experience confirms Paget's words, that the appearance of cancer often follows quickly after "deep anxiety, deferred hope, or disappointment." Cancer is more common in elderly persons than in children or young adults; the malignant growths of bone and other organs, which are not very rare in young children, are almost always sarcomata. It is not more frequent in men than in women, nor in the sickly than in the robust.

The embryonic theory of tumours.—According to Cohnheim, there is but one way in which a new growth can arise in an adult, and that is by a

portion of *embryonic tissue* having become arrested in its development during fœtal life, and having remained shut off until its dormant capacities have ultimately been roused into activity. Such an hypothesis was propounded by Virchow to account for the remarkable fact that enchondromata arise in connection with bones, but never from permanent cartilage; he supposed that a fragment of the original cartilaginous precursor of the bone might remain unossified, and might ultimately form the starting-point of a tumour. Cohnheim maintained that cancers are particularly apt to arise at spots which (as in the case of the orifices of the great mucous channels) are the seat of somewhat complicated processes in the development of the embryo, so that involutions of the external germinal layer may be supposed likely to occur there. The ultimate formation of the new growth he attributed to a failure of "physiological resistance" on the part of the normal tissues around. A somewhat similar notion was put forth by Thiersch in explanation of the liability of aged persons to keratoid carcinoma: he attributed it to the atrophied and inelastic condition of the fibrous texture of the skin at advanced periods of life, whereby he supposed the extension downwards of the epidermis to be facilitated.

There can be no doubt that Cohnheim's theory is readily applicable to certain kinds of tumour. It is probably true so far as the dermoid cysts are concerned; and it may perhaps account for the frequency with which growths arise in the uterus or in the breast of unmarried women in the later years of life, since in such persons the organs in question no doubt contain germs which fail to receive their normal physiological stimulus. In the case of the breast Dr Creighton has worked out a similar idea with extreme care and in great detail.* Having studied fully the normal process of evolution or "unfolding," which the mamma undergoes when preparing for its secretory functions, he finds that the growth of tumours in it may be regarded as a modification of that process, under what he terms "spurious stimulation," occurring at a time when the organ is in a quiescent condition.

It is obvious, though Cohnheim did not seem to think so, that such theories afford no explanation whatever of the mystery of tumour-development in general, or of the striking difference between innocent and malignant tumours. Why a fragment of embryonic tissue, after lying dormant for years, should produce a carcinoma or a sarcoma still remains entirely unexplained.

Moreover, there are facts to show that the theory of dormant embryonic masses is at least not universally true, particularly the relation of tumours to *injuries*, and to various local and accidental lesions. Cohnheim, it is true, altogether denied the traumatic origin of cancers. He cited Boll's statement that in 12 per cent. of the cases of cancer operated on by Langenbeck there had been an injury before the growth was developed; but he declared that such a mode of causation is impossible. He believed that his experiments on animals had enabled him to study all the morbid processes which are capable of resulting from injuries, and that such observations are final. The following cases related by Paget seem to prove the contrary.

A boy was accidentally wounded in one eye, which was sound. Within a few days, a medullary tumour grew from the eyeball; it was removed three weeks later, but it quickly recurred, and destroyed life. Another boy fell and struck his knee; swelling followed, which was at first supposed to be inflammatory; but it increased, and proved to be a large medullary growth

* 'Contributions to the Physiology and Pathology of the Breast,' 8vo, London, 1878.

round the lower end of the femur. A man at his work slipped and strained or broke his fibula; the injury led to pain and swelling, and in the course of eight weeks there was found to be a growth of large size outside and within the shaft of the bone.

Many instances can be cited in which a malignant tumour appears to arise out of some *chronic local lesion*. Thus it is well known that a keratoid cancer sometimes appears in the cicatrix of a burn on the arm or on the hand, where such a growth is otherwise rarely seen. A similar affection of the tongue often follows leucoplacia, or white syphilitic patches, at the end of several years. In the common bile-duct, a carcinomatous growth is very frequently traceable to irritation of its mucous membrane by gall-stones. And in more than one instance a malignant growth in the posterior wall of the urinary bladder has seemed to have been caused by the repeated introduction of catheters.

Cancer of the lip is apparently sometimes due to the irritation of a pipe; "chimney sweep's cancer" of the scrotum was almost certainly caused by the irritation of soot; cancer of the breast is often preceded by the kind of eczema of the nipple known as Paget's disease; and cancer of the glans penis is particularly common in cases of phimosis.

In the same way we may probably explain the predilection of malignant growths for the fauces, œsophagus, pylorus, sigmoid flexure and anus, the parts of the alimentary canal where mechanical friction is greatest.

Perhaps, however, these facts are not so incompatible with Cohnheim's theory as he himself supposed. Injury or irritation of a part gives rise to the formation of a new growth only as an exception; and it is surely not impossible that a dormant fragment of embryonic tissue which happens to be present may find in the injury or irritation the stimulus needed to rouse it into pernicious activity.

The cases in which it is most difficult to admit the embryonic hypothesis seem to be those of cancer in the scars of burns, and (on account of their frequency) those in which cancer follows white spots on the tongue, or in which cancer of the bile-ducts is set up by gall-stones.

SPECIFIC INFECTIOUS DISEASES

AFFECTING THE WHOLE BODY AND ACCOMPANIED BY FEVER

> Nunc, ratio quæ sit morbis, aut unde repente

Nosology—Bases of classification—General and local diseases—Specific Fevers.

IN arranging the order of diseases in a systematic treatise we cannot attempt a natural, perfect, or scientific classification.

For, in the first place, diseases are not comparable things. One is an anatomical change of structure; another is a pathological process; a third the result of the action of a mineral poison, a mechanical injury, or a parasitic animal or plant; while a fourth is only a frequently recurring series of concomitant symptoms, of which we know neither the material conditions nor the probable cause.

We might arrange diseases by the *regions* they affect; as those of the head, the breast, the belly, and the limbs; or by the *tissues* affected, as bones, joints, mucous membranes, skin; or by the *organs*, as brain, lungs, heart, liver. We should need a separate class for diseases which affect more than one organ, another for those which appear to affect every organ at once, and still there would remain diseases "of uncertain seat."

A *pathological* arrangement would group together diseases in which inflammation was the most important morbid process; those which consist of pyrexia without local inflammation; contagious and miasmatic diseases; degenerations of tissue; new growths—and so on as far as our knowledge of morbid physiology extends—whatever the region, tissue, or organ which these processes affected.

Or we might make an *analytical* arrangement, founded on the most definite and obvious symptoms; and consider successively all diseases which are characterised by a raised temperature, by dropsy, by dyspnœa, by jaundice, by the presence of albumen in the urine.

Lastly, an *ætiological* classification would put in one group those diseases which depend upon the invasion of animal or vegetable parasites, in another those which are produced by lead, mercury, or other poisons, in a third and fourth dietetic and climatic diseases.

But even if our knowledge of every "disease" were as complete as it is of alcoholic cirrhosis of the liver, syphilitic orchitis, aneurysm, scabies, or anthrax—if we had completed the task of Morgagni, and had discovered the seat and the cause of every malady to which the human race is liable—we should still find that no single principle of classification would give satisfactory results.

The object of medicine is to prevent, to predict, and to cure. These objects are sometimes best served by knowledge of morbid anatomy, sometimes by knowledge of processes, and sometimes by knowledge of causes.

Who is to decide whether so well understood a disease as lead-palsy will be best treated along with colic and other effects of plumbism, or with other forms of paralysis, or with wasting affections of the muscles, or as a peripheral neuritis? For different purposes each arrangement would be the best.

Every kind of classification which rests on a firm basis of facts is useful so far as it helps us to remember certain common characters of the objects classified, and mischievous if it is allowed to obscure other common characters upon which other classifications may be constructed.

In a systematic treatise, however, it is necessary to choose some one arrangement, and our choice should be decided by reasons of practical convenience. Our divisions need not be upon a uniform plan, but they should be few and plain. They should depend as little as possible on hypothesis as to the nature and causes of morbid processes, and as much as possible on clinical and pathological facts. And they should agree in the main with those traditional names and arrangements which do not contradict ascertained facts and which are generally accepted by the best authors.

When a clinical group of symptoms is found associated with a definite anatomical change in a given organ, it is best treated along with other "diseases" of that organ. When "it has no anatomy," it is most conveniently grouped with its nearest clinical allies. When it affects several organs, it should be referred to that which is its primary or most important seat. On these principles we make a chapter of diseases of the brain, the cord, or the nervous system generally. We are not afraid to place epilepsy near cerebral hæmorrhage, asthma not far from cancer of the lung, and rheumatism with osteo-arthritis. Diabetes might be classed with diseases of nutrition, with those of the nervous system, of the liver, or of the blood; but it may be reasonably placed in the neighbourhood of renal calculus, because these affections, differing in every other respect, agree in being both recognised by symptomatic changes in the urine. Rheumatism may be considered among the fevers, among general diseases, or among diseases of the joints; but the latter is the place where it is most conveniently compared with gout, and also where a reader would be most likely to look for it.

The general arrangement in the following chapters is local and anatomical, following the organs of the body; while functional diseases are, as a rule, placed with those presenting similar symptoms.

One important exception, however, has been made, in accordance with general practice.

There is a group of "general diseases" which, though variously defined and more or less extended, has been recognised from the earliest times. The type of this group is the disease with which we shall begin, typhus fever, as it was called, when that name only meant a variety of the genus fever. With it were associated other "continued" fevers, so called to distinguish them from the intermittent fevers common in Greece and Italy.

In recent times another group of diseases has been associated with continued fevers, the eruptive fevers or exanthemata: smallpox, measles, and their allies. These were classed with diseases of the skin, not only by Willan and Bateman, but also by Hebra, although they appear separately in the title of his work.*

* Measles and Scarlatina appear in Willan's 'Order Exanthemata' with Nettlerash and Roserash, Smallpox with Scabies, and Chicken-pox with Eczema. Hebra's treatise is entitled "Acute Exantheme und Hautkrankheiten," but Measles and Scarlatina appear after the

The presence of fever is, however, no sufficient criterion in itself. It may be produced by local inflammation or it may be idiopathic, it may be continued or intermittent, accompanied by a rash or not. Since the discovery of the important part played by microphytes in disease, as described above in the chapter on Contagion, it appears probable that idiopathic fevers and irritative pyrexia—perhaps we may add, inflammation itself, or at least purulent inflammation*—are alike due to the reaction of the organism when a brood of microphytes invade the blood and tissues.

Leaving, therefore, the old term "fever" to denote, not a disease or group of diseases, but a physiological state of which pyrexia is a synonym, we may unite the continued fevers and exanthems on the basis of their being contagious, and due exclusively to the entrance of living contagia. In a few cases, as noted in the chapter on Infection, we can identify the actual contagium; and, without venturing to push the argument from analogy, we may affirm that whether the contagium be a living microphyte or not, typhus and enteric fever, measles and scarlet fever, smallpox and chickenpox are each caused by the invasion of a specific particulate contagium.

But not only do they agree in this "specific" (*i. e.* special or peculiar) ætiology, they are all "general diseases." Some, like typhus, are without any local lesion but what is demonstrably the result and not the cause of the fever; while in others, like enteric and scarlet fevers, though local lesions are constant, they are clearly parts of a general process, and not its precedent cause.

Again, these contagious and general diseases agree in running a more or less defined (specific or peculiar) course, limited in time and developing periods of incubation, invasion, ingravescence, culmination, and defervescence.

Lastly, each of these maladies confers remarkable protection from a fresh attack while they do not protect from one another.

We have here therefore the most, perhaps the only, natural and scientific group of diseases, each separate and definable, yet agreeing with one another and differing from the rest.

Have any other affections than the traditional Fevers and Exanthems a right of admission to this class?

Accepting as the best criteria those of exclusive origin by contagion and of "breeding true," we have no difficulty in admitting the typically specific disease Mumps to the list, and, with almost equal claims, Whooping-cough and epidemic Influenza. Erysipelas and Diphtheria may probably be added, but there are difficulties in both cases which will be considered hereafter.

Syphilis never arises but by direct contagion; the contagium is particulate; it breeds true; it affects not only the blood, but, as Sir William Gull well put it, body, blood, and bones; it protects against itself; its invasion is accompanied by slight, occasionally by high fever, and by a characteristic rash. It differs from other specific fevers in the length of its course and in the difficulty of separating this course from what may be called its sequelæ. It also differs in the important fact of being hereditary.

Tuberculosis is like syphilis in being hereditary, and in its variable and

introductory chapters, between Seborrhœa and Erythema. Why dermatologists did not include Typhus is not apparent. It is as much an exanthem as Measles, and Measles as much a continued fever as Typhus.

* The late Prof. Hüter, of Greifswald, proposed to define inflammation as a septic process due to the entrance of microzymes which are so widely diffused that the disease is pandemic.

long-drawn course. It is still doubtful how far it can be called contagious, it does not affect every organ, and it certainly does not protect against itself. On the other hand, a definite bacillus probably occurs in all tubercular lesions, and in well-marked cases of acute tuberculosis the rapid course and general symptoms much resemble those of a contagious fever.

Pneumonia, *i. e.* acute lobar pneumonia, has strong claims on clinical grounds to rank as a specific febrile disorder. It has its micrococcus. It invades, runs its course and subsides like a fever. Its symptoms are scarcely more dependent on the hepatised lung, as to time and severity, than are those of enterica on the typhoid ulcers. But cases of contagion and an epidemic course are both exceptional for pneumonia. It is generally believed to arise from common causes, as exposure to cold; its course, though less variable than that of syphilis or tubercle, is far from constant; it is often secondary to other diseases; and it is not self-protective.

Cholera is another doubtful case. Few would now regard it as a mere local enteritis; such a conclusion would have less foundation than Broussais' doctrine that typhoid fever was only symptomatic pyrexia from ulceration of the bowels. Few doubt that it is contagious, as it certainly is epidemic; and this conclusion is independent of the pathogenic nature of Koch's comma-bacillus; for no diseases are more certainly contagious than typhus and smallpox, yet in neither has the microphyte, if it exists, been discovered. Usually there is little or no pyrexia in cholera, but there is reason to believe that this feature is rather masked than absent.

Two epidemic febrile disorders, contagious and once terribly destructive, have happily been banished from this country—the Sweating Sickness since the sixteenth, and the Oriental Plague since the seventeenth century. The latter without question, and probably the former is, like cholera, endemic and comparatively mild in certain localities; but, when epidemic, they acquire fearfully active properties.

Three specific diseases of the brute creation are occasionally transferred to man by inoculation,—they are, Anthrax or splenic fever, Glanders and Hydrophobia. In the first the microphyte is known and its whole history investigated; it answers every test of being the true contagium of the disease (*v. supra*, p. 13), so that other maladies may be compared with this as a criterion. Glanders is almost as certainly and completely known. The pathology of Hydrophobia is in many ways obscure and it is still classed with diseases of the nervous system, but there can be no doubt that its natural place is not far from Anthrax.

Another remarkable malady, as fatal as hydrophobia, is known by the cumbrous name of "acute yellow atrophy of the liver." This has many of the characters of a specific disease, although, like cholera, it is not as a rule a fever. At present it is best left with other hepatic diseases.

While we must admit, as undoubted members of this class, some affections in which no microphyte has been found, we must exclude others, though more or less certainly bacterial in origin, because they are not "general," or run no definite course, or do not protect. Gonorrhœa and Leprosy are instances. They are more properly grouped, the former with impetigo, some forms of erysipelas and other contagious suppurations (p. 15), the latter with lupus and other infective granulomata (p. 60).

Several of the above diseases are not included in the following section,

either because their pathology is doubtful or because they are more conveniently treated with local diseases.

Rheumatism, though a general disease, and febrile, is not contagious, does not protect, and has neither an exclusive or specific origin nor a constant or specific course.

In the following list are stated in a brief and, of necessity, dogmatic form, the characters of the several diseases which entitle them more or less decisively to a place in this section.

TYPHUS*

ἦξει Δωριακὸς πόλεμος καὶ λοιμὸς ἅμ' αὐτῷ.

Quoted by THUCYDIDES.

History, nomenclature, and geographical distribution—Incubation—Course: first week, exanthem; second week, crisis and convalescence: death and post-mortem appearances—Complications and sequelæ—Ætiology; contagion of typhus: its supposed spontaneous origin—Diagnosis—Prognosis—Treatment.

SCARCELY more than forty years have elapsed since this disease was finally separated from certain others with which it had been confounded. Yet we can trace back its history. For its prevalence as an epidemic, and the fearful mortality which always accompanies it, make it certain that many descriptions handed down by writers of former times refer to Typhus, unmixed with the other forms of fever from which it is now known to be distinct. Its place in history is next in importance to that of the true or Oriental Plague. It is the common pestilence which has accompanied and followed wars.

The name now in use was first applied to a malady, or a group of maladies, by Sauvages in 1759. Until then it had, from the time of Hippocrates downwards, been employed, in accordance with its etymology, to designate a confused state of intellect, with a tendency to stupor. Most probably the plague of Athens, recorded by Thucydides, was what we now call typhus. However this may be, there is no doubt of the nature of certain epidemic fevers which prevailed in Italy, France, and Hungary in the sixteenth century, and of which accounts were given by Fracastorius of Verona, and other contemporary writers. During the course of the same century occurred the first three of the famous "Black Assizes" in this country, when judges, sheriffs, and jurymen were suddenly attacked with fatal illness, which had spread from the prisoners brought up for trial. One of the older names of the disease is *jail-fever*. Another is *Morbus castrensis* or *military fever*, from the ravages which it has committed among soldiers and camp-followers, from the time of the Thirty Years' War and the siege of Reading in 1643 down to the Crimean campaign. Other names, again, are *spotted fever*, *brain fever*, *putrid fever*, from some of its more conspicuous symptoms. Of late years it has been universally called Typhus in this country and in France; but the Germans are obliged to term it *Typhus exanthematicus* or *Flecktyphus*, from their unfortunate habit of calling Enteric Fever *typhus*, instead of Typhus abdominalis or Ileo-typhus.

On the Continent the disease with which we are now concerned is much less common than in the British Isles. Both in Great Britain and in

* *Synonyms.*—Contagious or epidemic fever; spotted fever, febris petechialis, typhus exanthematicus; brain fever; jail fever, camp fever; fourteen-day fever. *Fr.* Fièvre typhus. *Germ.* Flecktyphus.

Ireland, it has prevailed with great severity on repeated occasions during the last two hundred years. Since the commencement of the present century there have been epidemics of Typhus in 1803, in 1817–19, in 1826–28, in 1836, in 1843, in 1846–48, in 1856, and from 1861 to 1870. It must be noted, however, that in some of the earlier of these epidemics there was a large admixture of cases of another disease, Relapsing Fever, which was not known to be distinct from typhus until 1843, but can even now be recognised by the small mortality which has always attended it.

Typhus is more or less endemic in the poor districts of Edinburgh, Glasgow, and Dublin, and was so until recent years in London. As an epidemic it has again and again left its haunts in cities and invaded the whole country. On the Continent and in the United States its course has been chiefly epidemic, and attendant on armies, especially during the miseries of sieges and of retreat. Typhus is rare even as an occasional visitant in the south of Europe, and it appears to be unknown in India and the tropics generally. It is not uncommon in Northern China.

The disease was introduced into America in 1847 by an infected immigrant ship, and in 1867 by the same means into Australia, but fortunately it has never established itself there.

Typhus is unknown among animals. Mosler injected fresh blood from patients with typhus into the veins of dogs without any result. Zülzer, however, has since been more successful; his injections were made upon rabbits, and he found that when the blood was taken while the disease was at its height those animals died in two or three days, but not if the crisis had been passed.

Entrance of the contagion.—No materies morbi has yet been detected, though there can be little doubt of its existence. It probably gains entrance in most cases by the breath, and successively invades the lymph, the blood, and the tissues through the stomata of the air-vesicles. The contagion is very sure, but readily diluted and dissipated, and probably not very persistent.

Incubation.—This is of variable length. Few cases afford an opportunity of determining it, for the disease rarely follows a single definite exposure to contagion. But Murchison collected for the 'St Thomas's Hospital Reports' in 1871 no fewer than thirty-one instances more or less directly in point. In two of them the effect was apparently immediate, and the same thing has been noticed by other observers: the patient having been conscious of an offensive odour proceeding from a case with which he had come into contact, was at once attacked with headache, prostration, nausea and rigors; and all the other symptoms developed themselves in due course. In one instance the period was not more than two days; in two, only four days; in one, from two to five and a half days; in one (that of Murchison himself) exactly five days; in one not more than six days; in two not more than ten days. Similar short incubation-periods have been given by other writers; thus Lebert, in 'Ziemssen's Handbuch,' states five to seven days; and some cases have been recorded in which the disease followed exactly eight days after exposure. On the other hand, Murchison found that in the larger number of his thirty-one cases the period was longer: in four it was exactly twelve days; in thirteen others it was within a few days of this, on one side or the other; and in four instances it was ascertained to be longer than twelve days; being in one patient not

less than thirteen days, in another not less than fourteen days, in the third exactly fifteen days, in the fourth not less than twenty-one days. The period of incubation would seem then to be very variable; all we can say is that it is a short one compared with that of many specific fevers.

During the incubation the patient appears to be well; sometimes towards its end, there is a little malaise, with headache, pains in the limbs, and loss of appetite. Lebert says that these symptoms may last several days.

Course.—The course of typhus is conveniently studied by dividing it into weekly periods.

First week.—The onset of the disease, from which the first week is reckoned, is generally definite, and sometimes sudden: more so than in enteric though less than in relapsing fever. The patient is attacked with headache and with pains in the back and limbs. He feels chilly, and sometimes shivers; after a while he may perspire, but the chilliness presently returns and he is glad to sit cowering over the fire. He feels weary and disinclined for exertion. He is thirsty, but appetite is completely lost. His tongue is œdematous, pale, and coated with fur, which is at first white, afterwards yellowish. There is nausea, but not often vomiting. The bowels are constipated. The urine is scanty, dense, and high coloured. He is restless and his sleep is disturbed by painful dreams and sudden starts. So far these are only the common early symptoms of any specific fever, and in slighter degree they attend a feverish cold. But then follow more characteristic symptoms.

Every day the patient becomes more prostrate; if unable to seek relief in bed, he totters as he walks, and his hands tremble when he attempts to use them; until, on the third or the fourth day at latest, he can support himself no longer.

From the first the patient's aspect is dull, heavy, and oppressed. The eyes are injected and suffused. The face is of a dusky colour, the flush being general, and not limited to the cheeks as in enteric fever. As the disease advances, the expression becomes more and more vacant and stupid, and it is seldom that the patient himself feels anxiety about his illness. Towards the end of the week there is generally *delirium*, especially at night. The advent of this symptom is said to be earliest in persons who have been intemperate, and in those who have been subject to mental anxiety and fatigue. In some exceptional cases it sets in during the first night, and Murchison speaks of having seen cases which were at first mistaken for mania. But, as a rule, it is only after the lapse of several days that the patient's mind begins to wander. About the same time he generally ceases to complain of headache.

The *temperature* rises rapidly in typhus. Wunderlich stated that it is generally 104°—104·9° on the first evening, and that by the fourth evening it is seldom under 104·9°, generally about 105·8°, and often higher still. But although Lebert has since observed 106·5° on the second evening, experience in England has been that the average figures are much lower than those given by Wunderlich. According to Murchison the highest temperature attained at any period of the disease is generally about 104° or 105°; it is scarcely ever as high as 106°, except in children, and it sometimes fails to reach 103°. The maximum is usually observed between the fourth and the seventh days, sometimes on the third day, and occasionally not until the second week. During the latter part of the first week, when the maximum

has been reached, the thermometer varies little. Murchison remarks that a high range of temperature in the first week generally forebodes severe cerebral symptoms in the second. Lebert observed that a rise in the evening is of comparatively little significance, so long as the thermometer falls each morning; what is really serious is a high temperature without intermission.

The *pulse* does not usually rise above 100 during the first two or three days; afterwards it ranges, as a rule, between 100 and 120. When it is much higher, the case is severe, if the patient is an adult; but in children a very rapid pulse even at the commencement of the disease is not an evil sign. Occasionally the pulse remains below 100, or even 90. Murchison cites instances observed by himself or by others, in which it was not above 40, and sometimes down to 28, for days together. In certain cases however of slow radial pulse, the heart's beats have been twice as frequent as the pulsations felt at the wrist. A slow pulse is not regarded as a favourable sign in typhus.

Respiration during the earlier days follows the pulse rather than the temperature.

The exanthem.—Typhus is attended by a characteristic *eruption*, the mulberry rash, as it was named by Sir William Jenner.

In rare cases this is preceded by a rose rash, which may almost be mistaken for the eruption of scarlet fever. In the museum of Guy's Hospital we have models, illustrating this remarkable roseola, which were taken from two women under the care of Dr Wilks in 1864. The parts represented are the abdomen, and the forearm with the hand; but in each instance the rash is said to have covered the patient. It was of a bright crimson colour, punctated, macular, or diffused. One of the women was a nurse in the hospital, so that she was under observation from the first. The roseola in each case faded before the mulberry rash came out.

The characteristic *mulberry rash* generally appears on the fourth or the fifth day of the fever; sometimes, as in a case admitted into Guy's Hospital in 1874, it may be discovered as early as the third day and sometimes as late as the sixth. Occasionally it is absent; but observations made with great care at the London Fever Hospital in 1864 showed that this occurred in scarcely more than 2½ per cent.—among nearly 2500 cases of all ages. The exceptions were mostly in children. When it does come out in them, it is often peculiarly abundant and well marked, so as to resemble the rash of measles; and in such cases it may be seen on the face, whereas in adults it is generally confined to the trunk and limbs. One usually looks for the typhus rash on the chest and the abdomen; but Dr Buchanan says that the earliest maculæ are to be found on the back of the wrists, the borders of the axillæ, and the epigastrium.

It consists of more or less numerous spots, of indeterminate form, the largest three or four lines in diameter, isolated or irregularly confluent. They may at first be slightly raised, so that one can feel them with the finger; and as they may then be of a somewhat florid colour, it is sometimes difficult, when they are few and separate, to distinguish them at this stage from the rose spots of Enterica. At this time, too, they disappear on pressure. But in the course of a day or two they alter in appearance; their hue becomes darker and more dingy; they are no longer raised; and when the finger is pressed upon them they either remain unaltered or assume a yellowish tint. This change is due to the escape of blood from the vessels into the substance

of the cutis; in other words, the maculæ have become petechial. They remain visible in the dead body if the case should end fatally while they are still present. In many instances they are from the very first of a livid or purple colour and do not fade on pressure.

Within forty-eight hours from its first appearance the mulberry rash is complete. During this time fresh spots may come out, but they are added to the old ones. There is not, as in enteric fever, a succession of crops of maculæ, one set appearing while another is fading away. Murchison satisfied himself on this point in a large number of cases, surrounding every spot with a circle of ink so as to identify it. In addition to the distinct maculæ, there is also a faint, irregular, dusky-red mottling, which looks as if it were more deeply seated, and has therefore been inaccurately called a "subcuticular rash." After the first day or two, no increase of the eruption occurs, but the maculæ persist until the end of the fever.

It is important to notice that the severity of a case of typhus is generally directly proportionate to the amount of eruption, its depth of colour, and the rapidity with which it becomes livid or petechial. Murchison adds that the exceptional cases in which no rash appears have generally a mild course; but according to Lebert they are often severe and sometimes fatal.

Second week.—This period is marked by a gradual aggravation of all the symptoms. The patient is now absolutely sleepless, and he usually passes into a state of continuous *delirium*. Sometimes he is noisy and violent, shouting, talking incessantly, singing, struggling to get out of bed, or fighting with his attendants. When spoken to, he becomes still more excited. In this condition a patient may throw himself out of the window, and some years ago a man was brought into Guy's Hospital for a suicidal wound of the neck inflicted in the course of typhus. After two or three days the delirium becomes quiet and muttering; and in the majority of cases it is so from the first. Sometimes excitement comes on as night approaches, while the rest of the day is passed in a state of stupor and prostration. By the middle of the week there is generally complete unconsciousness. When loudly spoken to, the patient perhaps opens his eyes and stares vacantly; if told to put out his tongue, he may separate his jaws, and leave them gaping, but no other signs of intelligence can be elicited.

Murchison, who himself went through two attacks of typhus, tells us that the imagination is far from inactive during the delirium of typhus. He took a great dislike to a nurse and to a valued friend; and because they once tied him down in bed, he fancied that they intended to murder him, that they were shutting him up in a dungeon, that they followed him to India, Burmah, and other countries which he had visited in former years, and to which he had escaped. Dr Gueneau de Mussey, who caught typhus in Dublin in 1843, afterwards remembered imagining that he was tied down in bed, and gradually consumed by spontaneous combustion, while women were taking water from a pond and pouring it over him. Another fancy was that he saw the front of a particular house in Paris in a state of phosphorescence, and a child suspended by the neck from a window. He also believed that he saw one of his friends killed in the street; and so strong was the impression that even during convalescence he continued to feel concern for his loss.

During the second week of typhus *deafness* is very commonly present; indeed, it begins about the fifth day. It sometimes affects one ear, sometimes both. Its cause is not yet ascertained. Stokes thought that it was

due to softening of the muscles of the ossicula; but to this view Murchison objects that the hearing is too soon recovered during convalescence. For many cases do well in which deafness has been complete; and from the time of Fracastorius there has been a tradition that it is a favourable sign. For this belief, however, there do not appear to be any good grounds; deafness is certainly present in many cases which end fatally.

The *pupils*, in the advanced stages of typhus, are contracted and insensible to light—as minute as pinholes, according to Graves. Jenner first laid stress on this myosis as a distinction between typhus and enteric fever; and Murchison says that, neither during active delirium nor in profound stupor, has he seen dilated and insensible pupils in typhus. Occasionally however when coma comes on, the pupils dilate.

The muscular *prostration*, during the second week of typhus, becomes extreme. The patient sinks down in bed, and lies on his back, unable to raise himself, or even to turn on either side. If the clothes are turned down to look for the maculæ, he takes no notice. One of the shrewd remarks of the last resident apothecary of Guy's Hospital, Mr Stocker, was that to find a fever-patient lying on his side was a good sign. The fæces are passed involuntarily. The urine dribbles away incessantly, so that unless it can be caught in a proper receptacle it soaks the sheets and produces great irritation of the skin. But before it begins to run off it may fully distend the bladder, the muscular coat of this organ being paralysed as well as the sphincter. One must, therefore, never omit to examine the hypogastric region at every visit, even if the nurse tells us that the urine is passed in abundance. Other results of muscular weakness are loss of power to speak, to protrude the tongue, and sometimes even to close the eyelids, so that the cornea may slough.

At this stage of the disease *tremor of the muscles* is almost constantly present. The whole body may be in a state of agitation, especially in old people and in those who have been exhausted by work or by intemperance; indeed, in drunkards a state of delirium tremens often seems to be added to the symptoms of the fever. Sometimes the tremor is limited to the hands and tongue. Murchison speaks of having sometimes seen nystagmus or choreiform spasms of the limbs. Much more frequent are those jerking movements of the muscles of the forearms which are commonly called *subsultus tendinum*. Or there may be twitchings of the face, one corner of the mouth being perhaps drawn up from time to time. Jenner saw two cases in which the face acquired a peculiar expression from a spasmodic action of the inferior recti muscles of the eyeballs in association with the levatores palpebrarum. In each instance the movements were excited when either of the arms was suddenly raised. Another variety of spasm is picking or fumbling at the bedclothes, for which we have the pedantic names of "floccitatio" and "carphology." In more rare cases the fingers are forcibly clenched, or the legs and thighs are bent so that the knees almost touch the chin.

The mulberry *rash* generally remains visible throughout the whole of this period. The maculæ may even become darker and more distinct, and may not disappear until the disease has already subsided. But the faint general mottling vanishes after a few days, and in mild cases, where this is the only eruption, nothing of it may be left at a time when the fever has still several days to run.

The *temperature* during the second week is, as a rule, rather lower than

in the latter part of the first week. Sometimes, indeed, the maximum is not reached until between the seventh and the tenth day. But during this period there is generally a slight fall, to which Murchison attached importance, believing that the cases in which it was absent were grave. Henceforth, and up to the time of the crisis, there are usually slight recurring remissions of one or two degrees. A decided rise during the second week indicates the supervention of some complication, generally pneumonia.

The rate of the *pulse* varies little from day to day, but its general tendency is to become more rapid. Its volume and force decline until in severe cases it is exceedingly feeble or even imperceptible. Sometimes it is dicrotic or undulatory, but Lebert remarks that this is seldom the case, whereas it is almost the rule in enteric fever. Irregularity of the pulse is not uncommon, and sometimes there are intermissions. Stokes pointed out an important sign of that progressive weakness which is the chief danger of the disease, namely, diminution or loss of the heart's impulse, with disappearance of the first sound. For several days, even when recovery is to take place, it is often impossible to feel the heart beating, and with the stethoscope only the second sound can be heard. In other cases a systolic bruit is developed, which no doubt belongs to the class of functional murmurs.

The *breathing* at this stage of the disease is almost always hurried, being at the rate of thirty or forty in the minute. According to Murchison, hypostatic congestion of the lungs should be regarded as a constant symptom rather than as a mere complication. It is, at any rate, present in all severe cases, and after death is scarcely ever wanting, whatever may have been the cause of the fatal issue. It commonly begins about the middle, but sometimes at the commencement of the second week. It is indicated by diminution of resonance over the bases behind, where the respiratory murmur is feeble, and by the presence of coarse râles, which may gradually spread over the greater part of the chest on both sides. Bronchial catarrh is always associated with this condition, and the patient may spit up considerable quantities of frothy tenacious secretion, mixed perhaps with streaks of blood. But sometimes cough and expectoration are entirely absent.

The *tongue*, in very mild cases, may remain moist and furred throughout the whole course of the fever. But usually during the second week it is dry, rough, and brown. When the disease is very severe it contracts into a ball, and becomes covered with a dark brown or black crust; this crust may be irregularly cracked; but the fissured condition of the tongue itself, which is so commonly seen in enteric fever, is rare in typhus. The lips and teeth are covered with a dirty blackish material, commonly spoken of as *sordes*. This consists of an accumulation of epithelial débris, which becomes dark from desiccation, or black from blood or from the remains of beef-tea and other food. An entire loss of appetite lasts to the end of the disease; and sometimes the patient refuses to take the nourishment which is given to him. At this stage he does not seem to suffer from thirst. Murchison met with some instances in which vomiting was a persistent and troublesome symptom, but such an occurrence is exceptional. The abdomen is sometimes flat or even concave, and tympanites is very rare. As a rule there is *constipation*, but looseness of the bowels is not infrequent. The fæces may be of normal consistence, and even if fluid, they are generally dark in colour. Murchison speaks of diarrhœa as occurring in about 5 or 10 per cent. of all cases of typhus. But in 1866 Dr Buchanan said that it had been seen in at least one third of the cases which had come under observa-

tion at the London Fever Hospital during some years previously; he was inclined to refer its greater frequency in the experience of some physicians to the larger amounts of liquid food forced upon the stomachs of their patients. Murchison remarks that when an aperient has been required the bowels often afterwards remain open or even relaxed.

The *urine* generally remains dark in colour during the second week of typhus, but sometimes it is pale and even alkaline. With regard to the amount of urea which is voided it is increased compared with the amount of nitrogenous food taken. At this period of the disease the *chlorides* fail to be excreted by the kidneys, even when the patient is made to take large quantities of common salt. The urine sometimes contains no chlorides at all, but Dr Buchanan says that usually two or three grains are passed in the twenty-four hours, just enough to produce an opalescence on the addition of nitrate of silver. *Albuminuria* is common in the febrile state generally, and in typhus appears to be present in more than half the cases.

Crisis.—Such is the condition of a patient suffering under typhus until about the fourteenth day, when, in favourable cases, a marvellous change takes place. Formerly, what was most often noticed was that he fell into a sound and quiet sleep, from which he awoke a few hours later, rational, refreshed, and cool. But at present the use of the thermometer enables us to watch the process more closely. In some exceptional cases there is a rise of perhaps two degrees the day before the crisis occurs. Much more often the temperature becomes slightly lower during the same period. The crisis itself is marked by a rapid fall to normal or even lower; a difference generally of from 4° to 6° Fahr. The fall may be complete within twelve hours, but according to Lebert it more often takes thirty-six hours and sometimes two or three days. Murchison says that in nearly one half of the cases of typhus the date of the crisis is the thirteenth or the fourteenth day; in more than three fourths it is from the thirteenth to the sixteenth. Lebert gives a much larger proportion of cases as subsiding between the tenth and the twelfth days, some even between the sixth and the ninth.

Complications may occasionally mask the crisis, or prevent its occurrence. They will be considered presently.

Crisis is sometimes accompanied by perspiration, or by diarrhœa, or by the excretion of urine depositing lithates in abundance; but there is no reason to suppose that such symptoms are essential to the defervescence, as was formerly supposed. Afterwards the temperature generally remains normal, except that for a night or two there may be a slight evening rise.

Convalescence advances rapidly. The tongue becomes clean and moist, and the appetite is ravenous. Within three or four weeks the patient often completely recovers his bodily strength and is able to return to work.

A true *relapse* of typhus is exceedingly rare. An instance of it was recorded in 1869 by Ebstein, the interval being twenty-five days. At the London Fever Hospital no such case occurred during twenty-three years after 1855. In that year Dr Buchanan had a nurse under his care who after recovering from an attack of the disease, was taken ill a week later, and went through it a second time: on each occasion there was a mulberry rash. The first fever appears to have lasted a fortnight, the second somewhat longer.

Exitus lethalis—Many cases of typhus do not run on long enough to exhibit a crisis. The mortality from the disease at the London Fever Hospital has been at the lowest 15 per cent. Murchison estimated that, if slight cases and those occurring in children be taken into account, it is about 10 per cent. It differs, however, slightly in different years, and it is said to be generally higher during an epidemic than at other times. Among soldiers in camp, or in a besieged city, the death-rate has sometimes been enormous. In the Crimea one half of the French troops who were attacked is said to have perished; and still more terrible instances are on record. In certain epidemics death has sometimes occurred on the second or the third day, or even after a few hours' illness. Such cases have been described as a special variety of the disease—*typhus siderans*, and the patient was described as *sideratus*, planet-struck. Murchison speaks of having seen several cases end fatally on the sixth or eighth day, usually from pulmonary congestion. But, as a rule, typhus does not destroy the patient until towards the end of the second week.

The exact mode of death varies. Sometimes it is by "typhoid" symptoms and coma; sometimes it is through the lungs by asphyxia; sometimes it is by failure of the heart, the pulse being imperceptible, and the skin cold, livid, and bathed in a profuse sweat. In some of the last-mentioned cases the patient lies for a day or more in a peculiar state, to which Jenner has appropriated the name *coma vigil*. He has his eyes wide open, so that he might be supposed to be awake, but he is absolutely insensible to all that goes on about him, and his face is devoid of expression. Sometimes death is preceded by a rapid elevation of temperature, as in a case at Guy's Hospital in 1873, in which the thermometer registered 108·7°.

Morbid anatomy.—The appearances observed in the bodies of those who have died from typhus are not characteristic of the disease, but are effects of the febrile state through which the patient has passed, and are found equally in cases of erysipelas, pyæmia, and other acute diseases. The *rigor mortis* is brief and incomplete, putrefaction takes place early, there is much cadaveric discolouration of the skin, the *blood* is fluid and dark coloured, and it stains the lining membrane of the heart and of the great vessels. There is often but little emaciation, yet the *muscles* are soft and friable, and when death has occurred at a late period of the fever their fibres are granular or waxy-looking under the microscope. A similar change is found in the substance of the *heart*, and probably often plays an important part in bringing about the fatal issue. The *spleen* is but little enlarged, weighing on an average seven ounces, though sometimes as much as fourteen ounces; but its tissue is very soft, and may be reduced to a mere pulp, which escapes when the capsule is divided. Jacquot is said to have observed a case in which instant death resulted from rupture of that organ. The *liver* is soft and hyperæmic: in an advanced stage of the disease it is often fatty. The *lungs* are in a state of more or less extensive hypostatic congestion. The affected parts are bulky, of a dark red or purple colour, and soft; serous fluid oozes abundantly from their cut surface, and from the opened bronchial tubes. There is, lastly, an entire absence of those intestinal lesions which belong to enteric fever.

Other changes which have been noted are quite independent of the disease. They are common either at a certain period of life, or in dissipated and intemperate persons, such as are apt to succumb to typhus. Thus the brain

has often been found atrophied, with an excess of fluid in its ventricles and upon its surface.

In other instances the *kidneys* have been wasted or in an advanced stage of Bright's disease. In such cases death is apt to be ushered in by convulsions, the occurrence of which in typhus should always lead at once to an examination of the urine; it may be then found to be albuminous, and may contain blood, more or less altered, and casts. Sometimes the renal affection appears to be quite early and recent, and probably is itself secondary to the fever. Murchison speaks of having found the kidneys weigh nineteen, twenty, or even twenty-three and a half ounces. It is to be remembered, however, that albumen may be detected in the urine of a large proportion of cases of typhus in which no cerebral symptoms occur, and which do well. It is usually in small quantities, and it is often present during only a day or two days towards the end of the disease.

Complications and *sequelæ* of typhus are neither numerous nor frequent. Jaundice is extremely rare. Murchison met with only fifteen cases in which it was present. In one of them the liver was in a state of acute yellow atrophy; and in another leucine and tyrosine were found in the viscera as well as in the urine. One well-marked instance of jaundice occurred at Guy's Hospital in 1869. The patient, a man aged forty-nine, died on the fourteenth day of the fever.

Lobar pneumonia is not very uncommon. Sometimes, when the patient appears to die of the severity of the disease, instead of there being merely hypostatic congestion of the dependent parts of the lungs, a considerable part of one of them is found to be hepatised. Either the lower or the upper lobe may be affected in this way. In other cases inflammation of the lung sets in a few days after the crisis. Of about forty consecutive fatal cases examined at Guy's Hospital, no fewer than six had well-marked pneumonia. In one instance an attack of pleurisy occurred a week after the subsidence of the fever; and after death the left side of the chest was found to contain several pints of fluid with flakes of lymph. Murchison has several times seen gangrene of the lung after typhus.

The occurrence of a convulsion is an unfavourable symptom, but even when it is repeated, an absolutely unfavourable prognosis is by no means to be given. Recovery took place in twelve among one hundred and thirty-two cases in which this complication occurred at the London Fever Hospital between 1862 and 1869. In very rare instances, where a fatal issue has occurred, blood has been found effused upon the surface of the brain; but this may have been the result of the convulsions rather than their cause. It is towards the end of the second week that convulsions are most often observed.

In very rare cases acute meningitis occurs as a complication. In addition to the cerebral symptoms which commonly accompany the fever, there is then retraction of the head, strabismus, and dilatation of the pupils. Mania sometimes sets in during convalescence, and may compel the removal of the patient to an asylum; but in the long run it seems always to end favourably. Hemiplegia, with or without aphasia, is an occasional sequela, but in all likelihood it depends upon embolism of one of the cerebral arteries by a fragment of thrombus derived from the left auricle or ventricle of the heart; for clotting of blood in the recesses of these cavities is doubtless of frequent occurrence during the height of the disease. Murchison once saw ulcerative

endocarditis in a case of typhus, with large vegetations and infarction of the spleen. Embolism of the arteries of the limbs is doubtless the cause of gangrene of the feet, which has now and then occurred as a sequel. Bedsores ought hardly to arise in this disease, since the state of coma is of comparatively short duration. Their presence sometimes accounts for the supervention of pyæmia, but in other cases blood-poisoning sets in during convalescence without any such obvious explanation. Thrombosis of the femoral veins is not often seen after typhus. Inflammatory swellings which have been called *buboes*, and compared with those that occur in the plague, occasionally form in the parotid and submaxillary regions, and go on rapidly to suppuration.

When a pregnant woman is attacked with typhus she not infrequently passes through the disease without interruption to the process of gestation, but sometimes a miscarriage occurs between the tenth and the fourteenth days. As a rule she afterwards does well, and the child, if not too immature, is generally saved.

Ætiology.—That typhus passes directly to other persons from the sick is established by the clearest possible evidence. Instances of such an occurrence are commonly observed in every hospital into which cases of typhus are admitted; if into general wards, those who are already patients with all kinds of other complaints are attacked; if into special wards, the medical attendants and nurses fall frequent victims. When cases are left in private houses or lodgings, the disease passes not only to relatives and to other inhabitants of the same dwelling, but also to doctors and clergymen, whose visits are only occasional. On the other hand, the removal of a single case of typhus from the building in which it arose is often effectual in preventing other occupants from taking it.

The diffusion of the disease can often be traced from point to point in a town or in a district. Thus Alison relates how the son of a shoemaker in Edinburgh lay ill with typhus in a room in which his father and two apprentices were at work. Afterwards both of the apprentices were attacked in their own homes, apart from one another, and at considerable distances from the workshop; and there followed seven cases of typhus in one house, and seven in the other.

An epidemic which occurred at Carlisle in 1781 was found by Dr Heysham to have started from a particular house in Richard Gate; one of the persons affected there was a weaver, who on his recovery communicated the disease to his fellow-weavers in a large workshop, and by them it was spread all over the town.

The contagion of typhus is probably exhaled both by the skin and the lungs, and it may perhaps cause the offensive odour which is so perceptible close to severe cases. This odour has been compared to the smell of rotten straw, or to that of mice. Murchison regarded it as *sui generis*; he says that he has known nurses in the London Fever Hospital distinguish typhus from other fevers by it alone. It is given off chiefly during the second week, and there is reason to believe that the contagion is less powerful before that time. The late Dr Perry, of Glasgow, maintained that the disease was not contagious before the ninth day. He found that at the Glasgow Fever Hospital patients who happened to have been sent in for erysipelas, pneumonia, bronchitis, or other inflammatory affections, escaped typhus so long as they remained in the wards for acute cases, but caught it

when they were transferred into a convalescent ward; and he adopted the plan of keeping such patients in the fever wards until they were sufficiently well to go to their homes, with the result that during several months none of them were attacked. Murchison, however, although he admits that typhus is most contagious after the first week, thinks that the spreading of the disease in convalescent wards is due to the patients coming more closely into contact there, but especially to their wearing their own clothes, saturated with the fever-poison before admission. He believes that the human body soon ceases to give off the poison after the subsidence of the fever.

It is, at any rate, certain that clothes and bedding may become vehicles (*fomites*) for the transmission of typhus. Murchison says that laundry-women are especially liable to contract the disease without direct communication with the sick. Barker and Cheyne, in their account of one of the first epidemics, relate that a child discharged from a fever hospital took to another institution a bundle of clothes which had not been disinfected; a woman who opened it perceived an exceedingly disagreeable odour, and in a few minutes became ill with what proved to be the beginning of the fever.* Very few positive instances seem to have been recorded of the communication of typhus by contact with the bodies of those who have died of it; but Murchison, when he was attacked in Edinburgh, had been dissecting in a close room, in which there were many such bodies, and he had never entered the wards of the infirmary, nor seen a case of the disease. On the other hand, at St Bartholomew's Hospital, in 1838–9, the dissecting room received seventeen bodies dead of typhus; but among six students of the hospital who alone took it, four had not dissected at all, and the other two, who had dissected, had been also exposed to contagion in the wards.

It appears that typhus is seldom conveyed by persons not themselves affected. But Murchison relates that in January, 1867, a patient in a surgical ward at the Middlesex Hospital was attacked after she had been there for four and a half months; and she had been receiving daily visits from a nurse who was in close attendance on a patient with typhus downstairs. Again in 1861, great interest was excited by the case of an Egyptian vessel, the "Shiah-Jehaad," from which typhus was introduced into Liverpool, where thirty-one persons caught it. Although Dr Duncan, on the testimony of the surgeons who attended the men on board this ship, thought that they suffered from no other disease than dysentery ('Trans. Epid. Soc.,' 1861), Dr Parkes came to the conclusion that typhus had really been prevalent among them before they arrived in port ('Army Med. Rep.,' vol. ii).

Typhus is not nearly so apt as the contagious exanthemata to be propagated by means of inanimate objects, or of human beings themselves unaffected by it. Moreover, its poison is easily rendered inert by free dilution with air. Some writers have stated that there is greater risk of the disease spreading from the lower to the upper stories of a house or of a hospital than in the reverse direction; and this, if true, would show that the upward currents of air that exist in all inhabited buildings are capable of carrying the infection with them. But experience has abundantly proved

* Haller, of Vienna, thought that dark-coloured materials were more apt to absorb the poison than light-coloured ones; I well remember, I used to notice, when demonstrator of anatomy, that the dissecting-room smell adhered to me more strongly when I wore dark clothes.—C. H. F.

But the 60th aphorism of Dr Keil, of Northampton, is that "Black cloaths *cæteris paribus* draw the least moisture of any" ('Medicina Statica,' 1720).

that it never passes from one house to another through the atmosphere. When the London Fever Hospital was one of a row of houses in Gray's Inn Lane, no case of typhus arose in the others; and afterwards, when it occupied its second site at King's Cross, on the same plot of ground as the Smallpox Hospital, and but a few yards off, Dr Tweedie was able to state that during eight years not one of the officials of the latter institution contracted typhus. So, again, Murchison says that if a patient with this disease is placed in a large, well-ventilated apartment, the attendants incur little risk, and the other residents in the same house none whatever.

Predisposing causes.—The facts stated in the last two paragraphs form links in an argument by which Murchison endeavoured to prove that typhus, instead of being always due to contagion from a previous case, is often generated *de novo* in persons placed under defective sanitary conditions, of which overcrowding is the chief.

It is true of other acute specific diseases, as well as of typhus, that many instances occur of which the origin cannot be traced; but positively to demonstrate the spontaneous origin of a contagious disease, is, from the nature of the case, almost an impossibility. Perhaps the most favourable opportunity that has ever occurred for investigating the point was afforded by the Egyptian ship, the "Shiah-Jehaad," already referred to. She left Alexandria in November, 1860, and, after calling at Malta, arrived at Liverpool on February 16th, 1861. But, according to Dr Parkes, some of the men may have brought the poison with them when they embarked at Alexandria; they numbered 476, and included not only Arabs, but also Nubians and Abyssinians. Of the supposed instances of the spontaneous generation of typhus collected by Dr Murchison, the most important, in consequence of the care and pains which he devoted to its investigation, is perhaps the group of seven cases which arose in Meridian Place, Bermondsey, in March, 1859—a time when the disease was at least very uncommon in London, for during ten and a half months previously only two examples had been seen in the Fever Hospital. But the real force of this and other similar observations lies in the fact that one single condition was traceable in every one of them, namely, that those who were attacked by the disease had been crowded and huddled together in narrow, ill-ventilated dwellings. They were often also destitute and famished; but that this is not so essential to the development of the disease as overcrowding, seems to be shown by the fact that at Dundee, in 1865, an epidemic of typhus was brought about by the inhabitants of the surrounding country flocking into the town in consequence of work being abundant and wages good. The occurrence of typhus in an epidemic form has, indeed, been predicted when, as in 1826 and in 1862, destitution and famine have been very prevalent; and such predictions have been verified by the result. It would be impossible to find a better illustration of the conditions under which, if at all, typhus is generated than was afforded by the "Shiah-Jehaad;" the men on board (who were being carried to Liverpool in order to navigate back to Egypt another vessel, a man-of-war, then in that port) seem to have been crowded together in the most shocking manner; some of them were in a state of starvation; the filth and stench between decks were abominable; and, to crown all, the hatches had been battened down on account of bad weather.

No less an authority than Virchow has endorsed the opinion that the poison of typhus can be generated by the concurrence of such conditions

as these; and the same view has been maintained by the late Dr Hudson, of Dublin. But all the facts adduced by Murchison may be brought into harmony with the opposite doctrine, namely, that the disease is invariably due to contagion from a previous case; for it is well ascertained that impairment of health increases the susceptibility of an individual to the typhous poison, and overcrowding is a powerful predisposing cause when the contagion is present.

It would seem, indeed, that everyone is originally capable of taking this disease, although the fact of having once passed through it affords an almost absolute subsequent immunity. At the London and Glasgow Fever Hospitals all the nurses who have not had the disease before contract typhus within three or four months after entering upon their duties. In 1833 Dr Tweedie stated that with one exception every physician connected with the London Fever Hospital had been attacked with typhus. Similar experience is recorded from the Fever Hospitals of Dublin, Cork, and Edinburgh.

It is sometimes possible to trace accidental conditions which favour the operation of the contagion; one is *intoxication*. Murchison says he has known several instances of persons exposed for months to the poison of typhus in its most concentrated form, who were not attacked until immediately after a debauch. Habitual intemperance probably acts in a similar way: it was once noted that more than one half of the patients admitted for this disease into the Edinburgh and Glasgow Infirmaries had led intemperate lives—but this perhaps was not conclusive evidence.

Other favouring circumstances are excessive *bodily fatigue*, *mental anxiety*, and *want of sleep*. Murchison, in support of the popular doctrine that a dread of typhus increases the risk of taking it, cites the case of an Edinburgh medical student who so feared it that he could hardly be induced to enter a ward in which there were any cases; he was one of the first students to be attacked during the epidemic of 1847. Again, the debility which accompanies convalescence from other complaints predisposes to typhus, and in armies it has been frequently observed to follow scurvy. There is no evidence that typhus is less likely to occur in phthisical persons than in others. Tweedie long ago made the remark that butchers appeared to be comparatively exempt from typhus. Most of the butchers admitted into the London Fever Hospital for the disease have been out of employment and ill-fed.

Poverty and starvation are among the most certain predisposing causes. No less than 95·76 per cent. of all the typhus cases observed at the Fever Hospital during twenty-three years, more than 18,000 in number, had been inmates of hospitals or dependent on parochial relief, and many of them had been on the verge of starvation for several weeks or months. Epidemics in Ireland, in England, and on the Continent have repeatedly been associated with the failure of crops and with the widespread destitution consequent; so that although relapsing fever is the true "famine-fever," that name was formerly given to typhus, and not without warrant.

Another, and the most important, predisposing cause of this disease is *overcrowding*. Beside its obvious influence in increasing the spread of typhus by contagion, there seems to be no doubt that it also augments the susceptibility of individuals to the poison. Thus it is quite possible that it may favour the occurrence of a first case among the occupants of a lodging-house or cellar, without generating typhus directly.

Other so-called predisposing causes probably act only by facilitating contagion. Thus epidemics occur rather in the winter than in the summer because the poor for the sake of warmth block up every hole by which air can enter their wretched dwellings during the cold season. But in some years it has happened that more cases have occurred in July, or in September, than in January. So far as is known, the variations of temperature which occur in temperate climates have no direct influence upon the prevalence of the disease. It is doubtful whether this form of fever has ever been observed in Africa, or in the tropical parts of America, although it was believed by some observers to occur in the gaols of India. If hot countries should prove to be exempt, it will not be possible to attribute the fact to any idiosyncrasy of the inhabitants, like that of negroes in respect of ague. For Africans and East Indians have been admitted into the Fever Hospital with characteristic symptoms of typhus.

It is worthy of notice that sometimes patients themselves attribute the disease to their having "caught cold" or got wet. Murchison says that this has been the case with a considerable proportion of the persons admitted into the London Fever Hospital. In 1856 a young man was taken into Guy's Hospital who gave as the history of his illness that he went for a long walk on damp ground, and felt that he took cold; two days later he had headache and fever, and the typhus eruption followed in due course. In that instance the poison had no doubt already been received, and the relation between the chill and the typhus was one of mere coincidence.

Age and sex.—Typhus may occur in persons at all ages, from one month to eighty-four years old. The quinquennial period at which the disease is most common is from fifteen to twenty; one-half of the cases admitted into the London Fever Hospital have been in patients from ten to thirty.

The proportion of males to females among typhus patients scarcely differs from that in the population generally.

Protection.—A second attack of typhus is as rare as one of smallpox; far more so than a second attack of measles or scarlet fever. It does, however, sometimes occur, and there was a notable instance of it in the case of Murchison himself, the interval between the attacks being ten years. He knew of two other physicians who contracted this form of fever twice, and in one of them it proved fatal on the second occasion. A very remarkable fact, for which he vouches and of which he saw at least six examples, is that, during an epidemic, a person exposed to the poison may have what appears to be an abortive attack of typhus, with fever, dry tongue, and even slight delirium, but no distinct rash; may recover, sometimes after exactly fourteen days, and then a few weeks later may go through a regular attack attended with the characteristic eruption. Such a "*typhisation à petite dose*," in fact, seems to afford no protection whatever.

Diagnosis.—This is seldom, if ever, doubtful when one has an opportunity of watching a case throughout its whole course; but there may be great difficulty in forming an opinion upon a single visit, or if the patient is brought to a hospital a day or two before his death.

(*a*) At the commencement of the disease, what suggests the correct view of its nature is generally the fact that there has been exposure to the specific contagion, or at least that cases have already occurred in the neighbourhood. Otherwise it could at first scarcely be distinguished from

smallpox and the other exanthemata, and not at all from enteric or relapsing fever, some cases of which begin exactly in the same way. As a rule all uncertainty is removed by the development of the eruption, but as a rare exception this may be absent, and sometimes, especially in children, it is by no means easy to say whether the rash is that of measles or of typhus. Lebert makes a point of the harassing cough which belongs to measles, whereas the bronchitis of fever is seldom troublesome. Certain cases which are commonly classed under purpura might also be mistaken for typhus; they are attended with eruptions which rapidly become petechial, and with much febrile disturbance; and they no doubt depend upon blood-poisoning, the exact nature of which, however, is not yet understood. Lastly, the copaiba rash has been mistaken for typhus, as in an instance quoted by Dr Hudson.

(*b*) At the end of the first week the diagnosis of typhus from *Enteric fever* is rarely a matter of serious difficulty, even in children. Apart from evidence of dates and the dissimilar exanthems, the one is epidemic and rapid in its evolution, while the other is sporadic and gradual in its onset and course. The condition of the abdomen and of the pupils is also a help.

Pneumonia, although formerly often mistaken for typhus, and although Murchison says he has seen many instances sent to the London Fever Hospital, can always be discovered by auscultation, which no careful physician would omit before giving a diagnosis of typhus in a patient without eruption. But it may still be a question whether pulmonary inflammation is or is not a primary disease. Murchison says that those cases of pneumonia in which the apex of the lung is first affected are particularly apt to be unattended with local symptoms, and to assume the mask of a "typhoid" condition.

The distinction between *meningitis* and typhus is one of far greater difficulty. Among the symptoms which point to the former disease are an anxious and pained expression of face, intense headache, especially when concurrent with delirium (for in fever pain almost always ceases before delirium sets in), the presence of convulsions early in the case, and the repeated occurrence of vomiting. The patient, moreover, is irritable rather than apathetic, and resents instead of enduring examination.

(*c*) Several further questions arise in the diagnosis of cases which come under observation at a time when the patient is comatose, with "typhoid" symptoms fully developed. Pyæmia may be mistaken for typhus under such circumstances; and if there be erysipelas, jaundice, or delirium tremens, it may be difficult to say whether these diseases are complications of fever or independent. In persons advanced in years, mere bronchitis is sometimes attended with a dry brown tongue, stupor, and other "typhoid" symptoms.

But the condition which is most apt to be mistaken for typhus at this stage is *uræmia*, dependent upon chronic disease of the kidneys. Murchison says that patients have often been sent to the London Fever Hospital whose symptoms were all of renal origin; and at Guy's Hospital in former years the doubts with regard to such cases have sometimes never been entirely cleared up. Conversely, in 1865, a man who was in a surgical ward for stricture became feverish and drowsy, and his illness was attributed to ascending nephritis, until a mulberry rash was discovered upon him; he died, and the kidneys were found to be healthy. It must be borne in mind that the existence of a chronic renal affection, when established by *post-mortem*

examination, affords no proof that typhus was not also present. According to Murchison, however, the thermometer generally affords a sufficient means of diagnosis; the temperature is at or below the normal in cases of Bright's disease, unless complicated with an acute inflammation.

Prognosis.—It is important to remember that the prognosis in typhus does not merely depend upon the severity of the symptoms. The most important consideration is the *age* of the patient. The older he is, the greater is the danger. In children it seems never to be fatal except by some com plication. Murchison found that at the London Fever Hospital (the average typhous death-rate for all ages being from 15 to 19 per cent.) the rate in persons above thirty was 35·39 per cent., in those above forty 43·48 per cent., in those above fifty 53·87 per cent., in those above sixty 67·04 per cent.

Again, typhus is likely to terminate fatally in persons who have been intemperate, who have been exhausted by fatigue of body or mind; or who have been suffering from privation of food. The greater frequency with which these various conditions occur among adult males, as compared with females, is probably the reason why the mortality is higher in them; among children between five and fifteen it is lower in boys than in girls. Murchison remarks that a presentiment of death is a very unfavourable, but not necessarily a fatal, indication. Patients who have gone on struggling against the disease during the first few days often become rapidly prostrate and die. The sooner they are put to bed the better their chance.

With regard to the prognostic significance of particular symptoms, the danger is best measured by the intensity of the cerebral disturbance and by the degree of prostration; the earlier the date at which severe symptoms are present the worse is the prospect. Sleeplessness continued throughout several days is of evil omen. So is the occurrence of convulsions. A very abundant rash is usually a bad sign, especially if the spots are dark and rapidly become petechial. A pulse over 120 is always a serious matter in an adult; and when it exceeds 150 death is almost certain to occur. Relaxation of the sphincters before the tenth day is unfavourable; but towards the end of the second week it is not uncommon in severe cases, which may nevertheless do well. Great lividity of the face and limbs and coldness of the distal parts of the body with profuse sweating are among the most threatening symptoms. A well-marked "typhoid" state, however, with dry, brown tongue, sordes, and subsultus is observed in many patients who recover. Indeed, even in what appear to be the worst cases, one must never give up hope until the last.

Treatment.—We as yet have no means of arresting the course of typhus, or of bringing it to a uniformly favourable termination; but a great deal may be done to increase the chance of a patient's recovery, and many of the most painful and distressing symptoms may be alleviated or checked. Murchison cites observations made both at Philadelphia and at Belfast, from which it appears that the death-rate from this disease was greater in proportion to the duration of the fever before admission into hospital.*

* It must not be supposed that neglect of medical assistance was the sole, even if it was the principal cause of the varying mortality in question; in many instances a fatal issue was doubtless the direct result of removing the patient at an advanced stage of the illness, whereas at an earlier period it might have done him no injury. Murchison says he has repeatedly known patients die from exhaustion after being carried for several miles in a shaking vehicle. But that, with proper precautions, a moderate journey may be effected

When typhus attacks a person in comfortable circumstances he may be safely left at home, provided that his apartment is spacious and well-ventilated, and that he can be properly nursed. But those who are poor should at once be carried to a hospital. The establishment of special institutions for the reception of fever cases dates from the commencement of the present century; but so recently as 1842 many London physicians, among whom was Richard Bright, were in favour of mixing such cases with others in general wards, rather than of setting apart special wards for them, or of collecting them in buildings devoted to that particular purpose. However, so far as typhus is concerned (and the same may be said of relapsing fever) this was certainly a mistake. For (1) it has now been proved by experience that if a sufficient cubic space of 2000 feet be allowed, and if ventilation be well attended to, the death-rate is not greater among typhus cases accumulated in the same ward than when they are scattered. (2) In every hospital in London where such cases have been placed in general wards there have been terrible examples of the spread of fever to other patients. To cite but a single instance: in 1862 one or two cases of typhus were admitted into one of the large medical wards in Guy's Hospital; seven other patients took the disease, and five of them died. What makes the argument stronger is that in a large proportion of medical cases, particularly in those of Bright's disease and of diabetes, the risk of a fatal termination, if typhus should be caught, is very much greater than among healthy persons. Moreover, the free ventilation, which is the chief condition of safety under such circumstances, is directly prejudicial to persons suffering from pulmonary complaints. It would be far safer to admit smallpox cases into a general ward than those of typhus, because protection against the former disease could easily be given by a general vaccination. (3) As far as medical men and nurses are concerned, the danger of the extension of typhus may be greatly reduced by retaining for as long a period as possible the services of those who have once passed through the disease, and by invariably selecting persons under thirty for all vacancies that may arise.

Every large town ought to have a fever hospital, capable of enlargement during an epidemic by the erection of temporary buildings; and all general hospitals should have one or more separate fever wards.

A patient suffering from typhus should be placed upon a spring bed, or upon a hair mattress, with not too many bedclothes. The temperature of the ward or room should not exceed 60°. After the first few days he should not be allowed to get up even to pass his excreta. It is important that his nurse should be strong enough to raise him when necessary, and instructed enough not to lift him into a sitting posture. From time to time he should be turned over to one side or the other, and kept from rolling back by pillows.

Food.—A nourishing diet is of the highest importance. Dr Graves, of Dublin, desired, as his own future epitaph, the testimony, "He fed fevers." So long as the patient can be tempted with food it is important to vary it as much as possible. Beside milk, eggs, and beef-tea, he may have broth made of mutton, veal, or chicken, meat-juices and extracts, jellies, custards, blancmange of isinglass or ground rice, white wine-whey, &c.; and vermicelli may be given in the beef-tea, small pieces of bread or toast in the broth, and arrowroot in the milk.

without risk appears from the fact that, among patients admitted into the London Fever Hospital from the immediate neighbourhood, the death-rate during five years was almost exactly the same as among those brought from the distant parish of St George's-in-the-East.

For beverages we have the choice of barley-water, toast-and-water, lemonade, tamarind-water, currant-water, effervescing drinks, and cold weak tea. Before many days have passed, however, he acquires a distaste for everything but cold water. The fever patient should drink often, in order to keep up free excretion by the kidneys.

Food must be pressed upon him and administered at regular intervals of from one to three hours; to give it more often than this is, according to Murchison, injurious rather than useful. If he be drowsy he should be roused for the purpose, and this can generally be done without seriously disturbing him; but if he should be sleeping quietly after having been very restless, the interval may sometimes be a little lengthened. It is, however, of great consequence that his strength should not be allowed to run down at night, or during the early morning, when the risk of exhaustion is always greatest. When, as is sometimes the case, he clenches his teeth, and obstinately refuses food, it must either be introduced into the stomach by means of a tube passed through the nostril, or, better, by closing one nostril and pouring the liquid nourishment through the other by means of a short funnel; an aural speculum answers the purpose well. If necessary, nutrient enemata or suppositories must be resorted to, and when there is obstinate vomiting there is no other plan open to us.

Stimulants.—The administration of alcohol is a very important part of the treatment. All observers are agreed that alcohol seldom need be given to children, that it is almost always required for patients over forty, and that persons whose habits have been intemperate must have it earlier and in larger quantities than others. The state of the heart affords the best indication; the necessity for stimulants is greater in proportion as the cardiac impulse is feeble, the first sound low, and the radial pulse rapid, compressible, or, above all, irregular. The propriety of continuing to give alcohol may often be determined by its effect on the heart's action. If the pulse becomes quicker than before, it is likely to do harm; if slower, it may be expected to do good. It is most needed during the second week; very seldom before the appearance of the mulberry rash. Low muttering delirium is often controlled by stimulants; a dry, brown tongue becomes moist, and other "typhoid" symptoms become less marked. On the other hand, severe throbbing headache and violent maniacal excitement are often aggravated. A burning dry skin is so far a reason for withholding alcohol; profuse perspiration, especially if the limbs are cold, calls for an increased supply. As a rule it should not be given when the urine, although scanty, is of low specific gravity, or when there is suppression of urine.

Probably there is no direct advantage in employing one liquor rather than another. Some recommend, on various grounds, brandy or whisky or rum, others port wine; Buchanan speaks highly of beer. The amount must vary with the urgency of the symptoms. Murchison thought that it was very rarely necessary to give more than eight ounces of brandy in the twenty-four hours, but some physicians order as much as twenty ounces. Of port wine as much as a bottle may be taken with advantage by patients who are desperately ill. But only small doses should be allowed at a time, repeated very frequently, at intervals of an hour or two; and when the daily quantity is large, the fact that milk mixes with brandy much better than with wine is a good reason for preferring it. When there is great prostration, with cold sweats, hot brandy or whisky-punch or hot wine-whey is recommended by

Murchison. At Guy's Hospital the house-physicians often inject stimulants under the skin in such cases, a practice suggested by Zülzer. Twenty or thirty drops of brandy may be administered in this manner. Ether, carbonate of ammonia, camphor, or musk may also be given by the mouth.

Treatment of symptoms.—The *pyrexia* itself seldom requires direct treatment in typhus. Probably, when the temperature rises high, cold affusion or the wet pack is better than cold baths.

Quinine in large doses of ten or twenty grains, although it lowers the temperature for a time, does no real good. Indeed, the experience of Christison in Edinburgh, of Peacock in London, and of Haller in Vienna was that quinine is positively injurious; and this was the final conclusion of the medical officers of the French army in the Crimean epidemic. Other antipyretic drugs—salicylates, thallin, antipyrin, antifebrin, are probably unsafe from their depressing action on the heart. This question will be again considered under Enteric Fever.

Murchison's favourite medicine at the London Fever Hospital was dilute hydrochloric acid, in doses of twenty minims, with a little syrup and tincture of orange. He often "observed the tongue become moist, and a marked improvement follow the commencement of the acid treatment, at whatever stage it was tried." When there is insatiable thirst, he recommends a very weak infusion of cascarilla or quassia.

The early *headache*, which is often a very distressing symptom, may sometimes be checked by an emetic. When the patient is young and robust, there is no objection to applying three or four leeches to the temples, and they frequently give complete and permanent relief. Or the hair may be cut, and the head be covered with a bag of ice, or a tubular cap through which cold water is running. In other cases a blister to the forehead is of service; or hot fomentations, as recommended by Graves, may be employed, especially in old or debilitated subjects. But in many instances it is advisable to prescribe opium for the relief of headache, particularly when it is accompanied by an inability to sleep.

Murchison says that *sleeplessness* at any stage of typhus, if it continues for two or three nights, is of itself sufficient to kill; and that whenever it lasts for thirty-six hours it should be combated by medicine. During the first week one may almost always give fifteen minims of Battley's liquor opii or a quarter of a grain of morphia at night, following this, if necessary, by another half dose two hours later. But at more advanced periods of the disease there is often danger in prescribing these drugs. When the patient is in a state of maniacal delirium, Murchison recommends chloral hydrate in a dose of twenty grains, which may be once repeated should the first draught not succeed. If this treatment fails, recourse must be had to opium, with which antimony may be usefully combined, as suggested by Graves. The chloral hydrate may also be given in some cases in which the delirium is low and muttering or like that of alcoholic origin; but when the heart's action is feeble or irregular, it does harm. Murchison then preferred opium as a sedative in conjunction with tincture of digitalis and sulphuric ether. Paraldehyde in half-drachm doses may be prescribed with the same object. Other useful sedative drugs are bromide of potassium, Indian hemp, and hyoscyamus. Each must be given in full doses to do any good.

When profound *stupor* appears to threaten the patient's life, Murchison advised that a cupful of strong coffee should be given every three or four hours. He also thought it important to use dry cupping to the loins, and

to apply mustard poultices, or flannels wrung out of hot water and covered with mackintosh, especially when the urine was scanty and albuminous. He believed that he had saved some cases by blistering the scalp with a piece of lint soaked in strong liquor ammoniæ, and applied for five or six minutes under oiled silk. Should high fever accompany coma, cold affusion to the head may sometimes be employed with great advantage.

For the *pulmonary complications* of typhus, ammonia is the chief remedy. But in some cases turpentine is said to be even more decidedly effectual; it is given in doses of fifteen minims every three hours. Mustard poultices should also be applied to the back and sides of the chest.

For *inflammatory swellings*, usually in the parotid region, both Murchison and Buchanan recommend the application of a blister at an early stage, for it sometimes appears to prevent the occurrence of suppuration. When an incision is required, it should be made early.

Convalescence.—After the subsidence of the pyrexia, the patient should be kept upon a restricted diet for the first two days; but upon the third day, if the tongue be clean, he may have a little boiled fish or chicken or the lean part of a chop. If wine or brandy has been given, beer should be substituted while the case is still under treatment, so that there may be no excuse for carrying on the habit of tippling when health is restored.

When pyrexia has disappeared, the patient, as a rule, recovers his strength as well as his appetite with rapidity. Relapses are excessively rare; neither A. P. Stewart, Sir William Jenner, nor Murchison met with a single case. Sequelæ, as deafness and phlegmasia dolens, are almost equally uncommon—in striking contrast to their frequency after enterica.

Moreover, while a tedious convalescence often leaves the typhoid patient weaker for years afterwards, typhus, like acute pneumonia, leaves no harm behind it. Hence the joys of returning strength are unalloyed by misgivings for the future. The contest with this disease is severe and often perilous, but it is neither protracted nor indecisive. *Horæ momento cita mors venit aut victoria lœta.*

RELAPSING FEVER

Λιμόν τε καὶ λοιμὸν γενέσθαι.—HERODOTUS.

History, nomenclature, and distribution—Incubation, onset and course—Relapse—Convalescence—Death and morbid anatomy—The spirillum—Famine as a predisposing cause—Diagnosis—Prognosis—Treatment.

TYPHUS, as described in the preceding chapter, is only the residue of the larger group of typhous "continued" fevers. The most important advance made by a long series of researches during the first half of the present century was the differentiation of enteric fever. At the same period a third fever also was discovered which is generally known as Relapsing or Recurrent Fever,* from its regularly consisting of two or more attacks separated by intervals of apyrexia.

According to Murchison, the distinction between this affection and typhus was first drawn in Ireland in 1826, when they both prevailed at the same time; but there is evidence that it also formed part of the epidemic of 1817–19, and of several earlier Irish epidemics, as far back as one recorded by Rutty as having occurred in 1739. Being far less fatal, and of shorter duration than typhus, it was in 1826 regarded as a mild variety of that disease. But in the year 1842, when it next appeared, Dr Henderson, of Edinburgh, brought forward good grounds for believing that it was a distinct fever and due to a different poison. The same view was strongly upheld by Jenner in 1849–51. The arguments used by these writers were chiefly three. 1. That the symptoms and course of the two diseases were different. 2. That even when they prevailed together in the same town, one could never be traced to infection from the other. 3. That neither of them afforded protection against a subsequent attack of the other. To these arguments may now be added (4) the fact that in relapsing fever the blood always contains a microphyte, which is absent in typhus; so that there is now no doubt of the specific and independent character of relapsing fever.

Since the publication of Henderson's and Jenner's papers, it has been ascertained that the same person often has relapsing fever more than once, so that we could not expect this disease to protect against typhus. But it has still been thought that typhus protects from famine fever. Dr J. C. Steele (then of Glasgow, now for many years our esteemed Superintendent at Guy's Hospital) remarked that, in the epidemic of 1848, persons who had previously suffered from typhus were not attacked by relapsing fever; and the same thing is said to have been noticed recently in epidemics at St Petersburg and at Breslau. Dr Henderson, however, related six cases in which typhus occurred first and relapsing fever afterwards; and Murchison says that of thirty-one persons who contracted relapsing fever in the London

* *Synonyms.*—Febris recurrens, typhus recurrens. Bilious remittent fever, seven-day fever, famine fever.. *Fr.* Fièvre à rechutes. *Germ.* Rückfallstyphus, Hungertyphus.

Fever Hospital in 1868–69 no fewer than thirteen were known to have had typhus.

At the beginning of the great epidemic of 1847–48, and also in 1851, it was particularly noticed, both in London and in other large towns of Great Britain, that most of the patients were destitute Irish, many of whom had recently left their own country; afterwards the English or the Scotch were attacked. Whether in 1842 the disease was derived from Ireland is not clear. The latest epidemic, that of 1868–71, seems to have had its origin in the east of Europe. There is no doubt that in 1847 relapsing fever had prevailed in Upper Silesia. With this exception it was unknown on the Continent of Europe, until in 1863 it was observed in Odessa, and in 1864 at St Petersburg. Next, in 1867, it broke out for the second time in Silesia, and in the following year it prevailed in Berlin and in other German towns, as well as in Breslau. In 1868 it reappeared in England. The first case, that of a woman of Irish birth who had been for several years in London, was brought into the Fever Hospital on the 4th of July. Four days later, another case occurred in the person of a Polish Jewess, who lived near to the Irishwoman. Three weeks later there arrived from the street in which the Jewess lodged a girl who had lived all her life in London. The only other persons who are known to have been attacked in London that year were eight German Jews; they all were admitted into the German Hospital at Dalston. But in October, a severe outbreak occurred at Tredegar in South Wales. In the autumn of 1869 relapsing fever became epidemic in several of the large cities of England; in London the disease reached its height in December of that year, and then gradually declined until June, 1871, when it finally disappeared. In Breslau it was again epidemic in 1872–73. In September, 1869, it appeared at Philadelphia, and in November at New York. The patients were chiefly poor Irish or Germans, and it seems to be almost certain that the contagion was imported from Europe, although its origin could not be discovered. On two or three former occasions it had been introduced into the very same cities by Irish emigrants, but it never showed any tendency to spread among the American population.

With regard to the occurrence of relapsing fever in Africa and in Asia, information is imperfect. Griesinger observed it in Egypt in 1851.* There is reason to believe that it has repeatedly prevailed in India, and the well-marked epidemic of 1877 at Bombay was carefully studied by Dr Vandyke Carter ('Med.-Chir. Trans.,' vol. lxi).

Incubation.—The period of incubation for this disease appears to vary; Murchison says that it sometimes breaks out immediately after exposure to contagion, sometimes not until fourteen days have elapsed. The usual period observed in this country has been four to ten days; in Silesia it was longer —a fortnight to three weeks. During the interval, no symptoms whatever are present; only in some very exceptional cases is there malaise.

Onset and course.—The attack generally begins with remarkable suddenness. The patient, while engaged as usual during the day, or perhaps on first waking in the morning, is seized with chilliness or with rigors; his head aches, he feels giddy, he has pains in the back and limbs, and his skin becomes burning hot. He grows rapidly worse and at once takes to bed.

* He saw a fever in Egypt which he called Bilious Remittent, and afterwards visiting London saw cases of undoubted Relapsing Fever and identified the two diseases, but it is not certain that he was correct.

One of the distinctions from typhus is that it is giddiness rather than prostration which prevents his keeping about. He is sometimes able to walk to the hospital two or three days after the seizure.

The thermometer indicates a very rapid rise of temperature. This begins even before the rigor, and within twelve or twenty-four hours it reaches 104° or 106°. The pulse, too, becomes quickened much earlier than in typhus; it is scarcely ever found below 110, and not infrequently it reaches 140 on the second day. The respiration is not quickened in proportion to the pulse and temperature. The tongue is moist and covered with a white or yellowish fur. There is great thirst. Appetite is generally wanting, but sometimes it remains good, or even voracious, the patient being able to take solid food without any harm resulting. In other cases, however, there is much nausea, and even vomiting. Pain, with tenderness on pressure, is often present in the epigastric and hypochondriac regions. By percussion increased dulness of the liver may be detected, and the spleen usually becomes decidedly enlarged, so that its edge reaches far below the costal cartilages. Jaundice sometimes occurs on or after the third day; in some epidemics it has been observed in one of every four or five cases, but generally not oftener than in one of eleven or twelve. It is now and then very bright, and the urine may be loaded with bile pigment; but the fæces appear always to remain dark. The face is flushed and the eyes are injected, but the countenance is not usually dusky, nor is the expression stupid and confused as in typhus.

As a rule, there is no exanthem; but several observers have noticed a roseola in certain exceptional cases, and in the epidemic in Silesia of 1857 a rose-rash on the second or third day was the rule. Murchison, who met with this in eight out of about six hundred cases, says that the rash consisted, of small spots, or of a reddish mottling, sometimes resembling measles, but more often undistinguishable from typhus at an early stage; yet always disappearing under pressure, and fading after a few hours or within three or four days at the latest. It came out sometimes during the first attack, sometimes in the relapse; and either as early as the third day, or immediately before the crisis. Petechiæ are not uncommonly present; no doubt fleabites have frequently been taken for them, but Murchison says that large numbers may come out after the patient's admission into hospital. The surface of the body often remains very dry, but sometimes on the second or third day there is profuse sweating which may last for hours without relieving the patient. Sudamina may be developed in large numbers, and are probably the cause of desquamation of cuticle which frequently occurs later on.

When relapsing fever occurs in a pregnant woman, gestation is almost invariably brought to an end, whatever may be its period; but it is curious that the abortion or miscarriage is not seldom delayed until the relapse. The child, if not stillborn, survives only a few hours. Here, again, there is a marked contrast with what occurs in typhus.

In the regular course of the disease, the patient's condition undergoes but little alteration for about a week. The temperature and the pulse remain high, though oscillating upwards and downwards a little, and the pulse-rate sometimes reaches 150, 160, or even 180. The patient continues to suffer from severe headache, often of a throbbing character, and from intense pains in the muscles and joints, much increased by movement. Murchison remarks that relapsing fever is altogether attended with far more

suffering than typhus; persons who have passed through both diseases invariably look back upon the former as the worse. Moreover, sleeplessness is almost always a marked symptom, and the mind generally remains clear although there may be a little delirium towards the end of the attack.

Crisis.—On the fifth or the seventh day as a rule the fever suddenly subsides. Sometimes, however, the crisis takes place as early as the third day, sometimes not until the tenth. Just before it, the fever often reaches its *acme*, touching a point higher than at any previous time; there may even be a rapid rise through as many as 4°. In some exceptional instances maniacal delirium suddenly comes on at this time; the patient screams and struggles violently, and passes his evacuations under him, but within a quarter of an hour becomes calm again and has no recollection of what has occurred. In other cases the crisis is said to be ushered in by epistaxis, diarrhœa, or the appearance of the catamenia. But the characteristic sign of the crisis is profuse sweating. The change is wonderfully complete. In the course of a few hours the temperature becomes normal, or even lower than normal, having fallen probably 8° or 10° without a break; Murchison cites one case in which there was a range of 13° in six hours, and another in which the difference amounted to 14·4° in twelve hours. At the same time, the pulse drops from 120 or more to about 70, the tongue becomes clean, and the patient loses all his pains. Lebert remarks that the period from evening to morning is that at which the crisis is most apt to occur. Litten has seen it sometimes preceded by a *pseudo-crisis*, the temperature falling below normal, but within twenty-four hours rising to as high a point as before, again to fall on the following day.

Interval.—During the *interval* which follows, the patient feels perfectly well. At first he is rather languid and exhausted; but his appetite is good, he quickly regains his strength, he gets up and walks about, and sometimes insists upon leaving the hospital and returning to work. His temperature for two or three days is almost always lower than in health; but afterwards it becomes normal. On the other hand, the pulse is at first rather above the natural standard; but at a later period it is often remarkably infrequent, perhaps not more than 44 or 50. Murchison remarks that in such cases it may rise to over 100 when the patient assumes the erect position.

Relapse.—In exceptional cases this apparent convalescence is in reality the end of the disease. But, as a rule, it is abruptly terminated, when it has lasted seven days, by a sudden reappearance of all the symptoms which had belonged to the first attack. Sir Robert Christison related a striking anecdote in reference to his colleague, Dr Hughes Bennett, who took relapsing fever at the commencement of the epidemic of 1843, when its characters were known only by the older members of the profession. "When he had detailed his case," being then supposed to be convalescent, "I told him he had sustained an attack of my old acquaintance . . . whose face I had not seen for a good many years; that he was not yet done with it, and that he would have another attack, commencing with rigor, on the fourteenth day" (of the disease). "Dr Bennett, surprised—I will not say incredulous,—replied that the relapse had no time to lose, as there were only three or four hours of the fourteenth day to run. It did, indeed, lose no time, for I must have scarcely reached home from his house before the rigor set in with violence." Sometimes, however, instead of occurring on the seventh day of the interval, the relapse begins on the second, or the third,

or the fifth day; sometimes it is postponed for several days, and even as late as the twenty-fifth day. Lebert says that it usually sets in at night.

This second attack is generally shorter than the first one, lasting three days, or not more than one or two; but sometimes it is prolonged to five days, and even to seven or eight. In the details of their symptoms and in their severity the two attacks may resemble one another exactly, but in some patients the relapse is the worse, especially when the original attack was very mild; in others it is far less severe, and it may be so slight as almost to escape notice. When well marked, it ends in a sudden crisis, just as before.

Recovery.—The patient now generally passes on to a permanent recovery, but sometimes there is a third attack, which begins between the twenty-first and the twenty-fourth days of the disease; it is almost always mild, and seldom lasts more than forty-eight hours. There may even be a fourth or a fifth attack.

Convalescence after relapsing fever is slow, as compared with that after typhus. The patient is a long time in regaining his strength. Notwithstanding that the duration of the disease up to the second crisis is only about eighteen days, he is seldom able to return to work within six weeks.

Sequelæ.—Relapsing fever sometimes leaves traces behind. Severe articular pains often continue during convalescence, and effusion into the knee- or ankle-joint has now and then been seen.

Another affection, which sometimes does not set in for several days, weeks, or even months after the subsidence of the fever, is a form of ophthalmia. This is described as beginning with an amaurotic stage, in which the retina, or perhaps the choroid, is alone attacked; afterwards, in what is termed the second or inflammatory stage, when the more superficial structures are involved, there is intense pain in and around the eye. It fortunately is rare for both eyes to be affected, for recovery is always tedious, and there is sometimes permanent loss of vision.

Protection.—As already remarked, relapsing fever seems to confer little or no immunity from subsequent attacks. All writers record instances in which persons have taken the disease two, or even three, times in the same epidemic.

Fatal event.—It is only in exceptional cases that relapsing fever proves fatal. Murchison states that in this country the mortality has been 4·03 per cent. In Bombay, however, Dr Vandyke Carter estimated it at 10 per cent. In persons advanced in years the disease is decidedly more dangerous than in younger persons.

Death occurs sometimes by sudden collapse. At and after the crisis the pulse is often weak, small, or irregular, and there may be temporary impairment of the first sound of the heart and of its impulse. These symptoms usually soon disappear, but the liability to their occurrence probably affords some explanation of the fact that a patient who may have had a mild attack, and who may have appeared to be doing perfectly well, is now and then found pulseless, cold, livid, and unconscious, and dies in a few hours. This sometimes takes place at about the period of the first crisis, but sometimes during the interval. In three such cases, observed by Murchison, the heart was found fatty and dilated. Another mode of death is by suppression of urine leading to convulsions and other cerebral symptoms. In some instances of this kind, recorded by Dr Henderson as far back as 1843, Dr Maclagan

discovered urea not only in the blood, but also in fluid from the cerebral ventricles. It is probable that in these cases the kidneys were diseased and that albuminuria was present during life; but the urine may contain albumen, and even blood, in relapsing fever, without any serious consequences resulting. Again, there is a variety of the disease attended with typhoid symptoms, and invariably accompanied by jaundice, which often terminates fatally; this Griesinger described as a distinct "bilious" form of fever. Among his symptoms are hæmorrhages into the skin and from various mucous surfaces, including that of the stomach, so that the vomited matters may be black, like those of yellow fever. The interval is imperfectly marked, the pyrexia running on more or less continuously from the first attack to the second. As, however, Heydenreich, in St Petersburg, and Carter, at Bombay, have each shown that the spirillum was present in cases of this kind, there is no doubt that they belong to relapsing fever.

Anatomy.—The *spleen*, if death occurs during the attack, is found to be more or less soft and much enlarged, more so than in either typhus or enteric fever. Küttner is said to have found this organ four and a half pounds in weight. It sometimes contains embolic wedges. In the one case which came to an autopsy at Guy's Hospital during the epidemic of 1869–71, the spleen, which weighed fifteen ounces, had a remarkable appearance. It contained a number of small yellow softened patches or abscesses, the largest being of the size of a horse-bean, which seemed to follow the branchings of minute veins. Dr Moxon could discover no thrombi in any of the vessels, even with the aid of the microscope. Very similar appearances were observed by Litten, at Breslau, in the epidemic of 1872–73. The *liver* is also increased in size. As a rule, the *kidneys* are gorged and swollen, and the epithelium in the renal tubules is in a state of cloudy swelling.

In some cases relapsing fever proves fatal through some secondary complication. Thus pneumonia has, in certain epidemics, been rather frequent, as, for example, at Breslau in 1872–73. Lebert says that it was generally double, that it occurred chiefly in those who had been intemperate, and that it sometimes set in during the attack, sometimes in the relapse. It has been known to lead to pulmonary gangrene. Bronchitis is commonly present, but is seldom severe. In St Petersburg hæmorrhagic pachymeningitis is said to have been observed. The spleen has sometimes ruptured, discharging a quantity of blood into the peritoneal cavity, and causing death by rapid collapse. In other instances an embolic block in this organ has broken down and set up fatal peritonitis or pleurisy. Another cause of peritonitis may be dysentery, which has been a frequent and a very dangerous complication to some epidemics. The occurrence of abortion is sometimes fatal by profuse hæmorrhage, or by rapid sinking. Inflammatory swellings or "buboes" in the parotid regions or in the groins are said to have been often the cause of death at St Petersburg, but in England they appear to have been more frequent in cases which recovered.

The pathogenic microbe.—Relapsing fever is remarkable as the first specific disease in which the contagion was discovered and its pathogenic significance demonstrated. This microzyme is morphologically a vibrio (p. 14),

and has been named *Spirillum Obermeieri*,* after the late Dr Obermeier, of Berlin, who first described them in 1873, although he had observed them as far back as 1868. It seems doubtful whether the form found in the blood of relapsing fever is identical with that which had previously been observed in water containing vegetable matters (*Spirochæta plicatilis*, Ehr., Cohn) and in the saliva of healthy persons (*S. denticola*). Dr Vandyke Carter says that the dimensions of an organism of this kind which he found in the water of a tank at Bombay were much larger than those taken from his fever patients ('Med.-Chir. Trans.,' vol. lxi).

Its ordinary appearance is that of a delicate, homogeneous, spirally-twisted filament; its length is from $\frac{1}{2000}$ to $\frac{1}{500}$ of an inch, or equal to from one and a half to six times the diameter of a red blood-disc (*circa* 15—40 μ). It is never still, and its motion is compounded of a rotation on the long axis, a progression forwards or backwards, and a lashing movement, which lengthens it out and causes the twist for a time almost to disappear.

All observers admit that the presence of the spirilla is coincident with the attacks of relapsing fever, and that during the interval or intervals it cannot be detected. Birch-Hirschfeld, however, once found it for two days after the second crisis, and several writers, including Litten, have stated that it is seldom to be seen during the first two or three days of the disease.

Heydenreich, of St Petersburg, who has made what seems to have been a careful series of investigations, declares that while it appears before the thermometer begins to rise, it ceases to be discoverable before the commencement of the crisis. He has specially inquired into the influence of heat upon this organism outside the body, and he finds that it remains alive, as evidenced by the persistence of active movements, much longer when it is kept at a temperature of 60° or 70° F. than at blood-heat, whereas at fever temperatures it dies more quickly still. His hypothesis accordingly is that the pyrexia, which is itself caused by the existence of this organism in the blood, proves directly fatal to it. In all probability the filament breaks up into a number of minute granules, and some of them may perhaps constitute the germs from which fresh crops of spirilla are afterwards developed. Heydenreich has occasionally seen some of the filaments beset with granules so as to resemble a necklace, and the late Dr T. R. Lewis, of Calcutta, speaks of having once noticed a beaded appearance. If the germs remain alive in the blood throughout the whole of the interval, they must possess the attributes of *Dauersporen*, for the spirochæta itself dies at the temperature of the blood in about twenty hours.

Even during a single attack, Heydenreich finds that there are extraordinary fluctuations in the numbers of these microphytes from day to day. He therefore supposes that successive generations are more or less constantly produced throughout the fever. Sometimes after they have been present for two or three days, they suddenly cease to be discoverable; but a few hours later they reappear in greater or less abundance. Their recognition in the blood, at the end of an interval, has repeatedly enabled him to foretell the approach of a relapse, which, however, he admits may be so slight as to be scarcely noticeable. On the other hand, Dr Carter says

* Others refer it to the genus *Spirochæta*; for Ehrenberg in 1833 distinguished two genera of *schizomycetes* under these names, the difference between them being that *Spirochæta* possesses greater flexibility than *Spirillum*. This distinction is preserved in the nomenclature of Cohn and Flügge, but the two "genera" are closely allied and the names are applied almost indifferently to the microbe discovered by Obermeier.

that at Bombay he sometimes detected the spirochætæ at periodic dates, when there was absolutely no rise of temperature; while in other cases a one-day febrile attack would occur at the proper time for a relapse, without the blood containing the organism. This observer remarks that the numbers of them must often amount to hundreds of millions, dozens being seen in the field of the microscope at the same time. It even seems likely that they may become aggregated together into dense masses with blood-corpuscles, and seriously interfere with the circulation. In fatal cases they cease to be discoverable after death. None of the solid organs have hitherto been found to contain them. Heydenreich could not detect them in the urine, nor in the conjunctival secretion, in the fluid from the pleura, the intestine, or the bronchial tubes.

Spirochæta (*v. Spirillum*) *Obermeieri* has been successfully cultivated out of the body, but for a long time all attempts to reproduce the disease failed. Injections of blood infected with it into the circulation of dogs, rabbits, or guinea-pigs were made by Obermeier himself without result, and the same negative result followed inoculation of sheep. Nor did he find that the disease was propagated by the penetration of minute quantities of blood from patients with relapsing fever into scratches upon the hands of healthy persons. Dr Carter has since recorded the fact that a few days before he himself was attacked he had scratched his finger in making an autopsy upon a fatal case. Finally he succeeded in inoculating monkeys with the spirillum taken from the blood of patients suffering from relapsing fever. The organisms were found after death in the viscera of the animals experimented upon ('Lancet,' 1879 and 1880). This completed the chain of evidence, and we may henceforward regard this vibrionic fission-fungus as the contagium vivum, and the sole cause of relapsing fever, according to the criteria laid down on p. 13.

Mode of spreading.—Direct contagion from the sick is the chief mode of propagation of this disease, and it is exceedingly apt to pass from hospital patients to nurses and clinical clerks. In 1843 the post of house-physician in a fever hospital at Edinburgh had to be filled six times in five months, owing to successive incumbents being attacked. In the London Fever Hospital, during the years 1869 and 1870, twenty-seven of the nurses and officers, and five patients admitted for other diseases, contracted relapsing fever. In 1870 a nurse from the Fever Hospital was transferred to St Mark's Hospital for fistula; and about the same time a wardmaid from St Mark's paid a visit to the Fever Hospital. These two women both fell ill at St Mark's, and gave relapsing fever to five other persons there. Two striking instances of direct contagion were recorded by Mr Reid, of Glasgow, in 1843. (1) At Dalmarnock Colliery there was a large building consisting of three stories, which was entered by separate stairs and contained forty families; some Irish people brought relapsing fever with them into a single apartment on the uppermost flat, whereupon it spread from room to room, and ultimately descending a stair, attacked twenty-two individuals in the space of two months. (2) Into a house of two apartments, in which eleven human beings were lodged, a person from a neighbouring village introduced the fever; every person there fell ill, but all the occupants of the next house, separated only by a brick partition, escaped, although they were almost as closely crowded together.

That the disease may be transported to a distance by infected clothes seems to have been proved by two cases recorded by Dr Parry, of Phila-

delphia, in 1870; and in 1843 it was noticed in Edinburgh that a large number of laundry-women contracted relapsing fever, although they had no other communication with the sick than washing their clothes and bedding.

Litten has related how a mason, who himself remained well, but who slept in a street in Breslau in which the disease was prevailing, carried the contagion to his mother, who lived where no case had before appeared.

The facts of this Breslau epidemic of 1872–3, which are to be found in the 'Deutsches Archiv' for 1874, strongly support the conclusion derived from experiment, that the spirillum (or its spores) is the sole and constant agent in spreading the disease. In all probability they are given off either with the breath or from the skin, and are received into the air-vesicles with the inhaled air. Litten has clearly shown that at Breslau they were not conveyed in drinking-water.

Predisposing cause.—The cases observed by Litten in Silesia seem to have belonged to the poorest classes, with the exception of the medical men who took the fever in the hospital; and English writers have generally regarded as the cardinal fact in the ætiology of this disease its occurrence in those who have been starving. It is the *famine fever* of Ireland. Murchison cites instance after instance to prove that those who have suffered from it in England and in Scotland have, with certain exceptions, been in a state of extreme destitution. When it occurred in Silesia in 1847, the inhabitants, in consequence of a succession of bad harvests, had been reduced to subsist on clover, grass, mushrooms, and the roots of trees. Carter states that it was brought to Bombay in 1877 by the peasantry flocking into the city from famine-stricken districts. History shows that as Typhus is the pestilence of war, of camps, and of sieges, so Relapsing fever is the pestilence of famine.* Relief of extreme destitution in districts where relapsing fever was prevailing has repeatedly been followed by the subsidence of the epidemic. Starvation renders persons more susceptible to the contagion, either by weakening the power of the living cells of the body to cope with the invading microbes or by favouring the development of the latter more directly.

Age and sex.—Relapsing fever may attack persons of all ages, from five months to seventy-five years, but the majority of cases are between the ages of fifteen and twenty-five. There are more male than female patients, the reason probably being that more men than women are beggars, hawkers, and vagrants.

Diagnosis.—It is only at the commencement of relapsing fever that its diagnosis in ordinary cases presents any difficulty. Murchison remarks that during the first two days one may be scarcely able to distinguish it from smallpox; but in consequence of the frequency with which it prevails epidemically at the same time with typhus, the early differentiation of those two

* Murchison believed that the specific poison of the disease might be generated *de novo* in the human body as the result of inanition. He cited the observations of Holland and of Donovan to prove that persons in a state of starvation suffer from delirium, stupor, and coma; that they may have a quick pulse, a dry tongue, flushing of the face, intolerance of light, and neuralgic pains over the body, and that they exhale putrid odours from the skin. He believed it to be a point in favour of such a view that tramps have often been found to bring the disease with them into London after sleeping by the roadside under hedges. Dr Carter also says that one of the earliest cases he saw in Bombay was that of a destitute lad who, while tramping up from the famine district of Poonah, was seized with fever in the upland country, and was barely able to crawl into the hospital on his arrival at Bombay. But it is obvious that in none of these instances could the reception of the disease by infection be positively disproved.

diseases, so unlike one another in the danger which they entail, is important in practice. How useful for diagnostic purposes the detection of the spirochætæ may be, has been shown by Dr Carter at Bombay, where there was often difficulty in distinguishing the effects of malaria from the more continued varieties of relapsing fever, corresponding with the "bilious typhoid" of German writers. This observer states that so multiform were the phases and degrees of the spirillum fever that about 25 per cent. of his cases could properly be termed irregular.

Prognosis.—Most patients attacked by relapsing fever recover. It is far less fatal than typhus or enterica. Out of 441 cases collected by Murchison from the records of the London Fever Hospital only 11 proved fatal; and in the great Scottish epidemic of 1843, of 6300 cases only 260 died. On a basis of over 14,000 cases he estimates the mortality at less than 5 per cent. As usual in epidemics, the worst cases come first and the disease becomes gradually milder. Age is the most serious adverse circumstance, as in typhus and enteric fever. Hæmorrhage, a petechial rash, delirium and scanty urine are the most grave symptoms.

Treatment.—This is not so successful as might be hoped, for we have as yet no means of preventing the relapse. With this object quinine and arsenic have been employed both in England and in Germany in vain. At Breslau carbolic acid, and in America the sulphites, the hypo-sulphites, and the preparations of chlorine have been used with no better result. It remains to be seen whether the salicylate of soda, or the sulphocarbolates, or perchloride of mercury, or some other of the parasiticides of antiseptic surgery may be more effectual. According to Murchison patients often find great comfort from frequent sponging of the surface with cold or tepid water, and from cold affusion on the head. An emetic at the first onset of the disease affords much relief to the severe pains in the hypochondriac regions. Throughout the febrile attacks castor-oil, or some other mild aperient, should be given when necessary. Murchison also recommended the systematic administration of diuretics, by which he believed that it was often possible to prevent one of the chief dangers of the disease, the supervention of uræmic poisoning. He directed that from one to two drachms of nitrate of potass, one drachm of dilute nitric acid, and half a drachm of tincture of digitalis should be taken in divided doses in the twenty-four hours. He allowed rather a liberal supply of food, and to persons beyond middle age he administered stimulants about the period of the crisis, especially when he suspected that the heart was weak. He often found it necessary to give opium for the relief of headache, or of the muscular and arthritic pains which cause so much distress, but states that the hydrate of chloral proved a useful substitute. Lebert recommends frictions with a liniment of chloroform and oil for alleviation of the pains in the limbs.

On account of the contagiousness of relapsing fever, it is important that patients should be taken to a hospital as early as possible. They should be placed together in wards set apart for the purpose, since Litten seems to have shown that the accumulation of a large number of cases together neither augments the mortality of the disease nor increases to an appreciable extent the danger of its spreading to medical attendants and nurses.

ENTERIC FEVER*

Ac dum prima lues udo sublapsa veneno
Pertentat sensus, atque ossibus implicat ignem
Necdum animus toto percepit pectore flammam.
VIRGIL.

*History of the recognition of Enteric Fever and of its distinction from Typhus—Its extent—Nomenclature—Incubation—Clinical course and symptoms—Recovery—Abortive cases—Fatal cases—Complications—Sequelæ—Relapses—Protection—Diagnosis—Morbid anatomy—Ætiology—A contagious disease, always produced from a previous case—Methods of contagion: by air, water, &c.—Predisposing causes: soil-water, climate, age—Prognosis—Treatment—Food, stimulants, drugs—Cold baths and antipyretics—Treatment of other symptoms—Convalescence—*FEBRICULA.

ALMOST at the beginning of the present century, the study of morbid anatomy in Paris was rewarded by the discovery that in the bodies of those who died of fever in that city the intestines were inflamed and ulcerated. The true bearings of such observations were not, however, at once fully appreciated. Broussais and others maintained that a "gastro-entérite" was the essential cause of "continued fever." Presently the suggestion was made by Serres and Petit that the intestinal lesions were specific, and resulted from the introduction of a poison into the system, and that they were of an eruptive nature, like the pustules of smallpox. Bretonneau, of Tours, noticed in 1826–29 that they were specially localised in the solitary and the agminated lymph-follicles of the intestine. He endeavoured to introduce the name "dothienentérie" (δοθιήν, a pustule, and ἔντερον, intestine) for the fever in which they occurred. This clumsy term was used by his pupil Trousseau, but it never met with general acceptance. Unfortunately, much greater success attended a proposal made by Louis, in 1829, to designate it "fièvre typhoïde." This proposal was, at least in England, universally adopted; and it greatly impeded a right understanding of the matter. Up to that time, all the French physicians who had written upon the intestinal affection had assumed that the same lesion would be found in every form of the disease known by the various names of typhus, putrid fever, bilious fever, gastric fever, jail fever, &c. But when the morbid anatomy of patients who had died of fever came to be investigated in Scotland and in England, the bowels were often found to be healthy. For a time the difference was supposed to be accidental, or of little consequence. But gradually it became apparent that two distinct diseases had been confused together. The credit of indicating the clinical distinctions between them is divided among a number of observers; Gerhard, of Philadelphia (1836), Lombard, of Geneva (1836), Shattuck, of Boston (1839), and particularly

* *Synonyms.*—Typhoid Fever, Gastric, Pythogenic, Infantile remittent Fever, Slow nervous Fever of Huxham (1739), Fall Fever (U.S.A.).—*Fr.* Fièvre typhoïde. *Germ.* Typhus abdominalis or Ileo-typhus.

A. P. Stewart, of London (1840), deserve mention.* Louis, in the second edition of his work, published in 1841, expressly announced that his "fièvre typhoïde" and the typhus of English writers were very different. There were, however, many who maintained the opposite view, that the two forms were identical. The ultimate issue of the controversy still appeared uncertain when, in 1849–51, Jenner published a series of researches, based upon observations made at the London Fever Hospital. The peculiar value of his papers lay in the proofs which he brought forward of the fact that the different forms of fever owe their origin to distinct specific causes. During two or three years he investigated with great care every instance in which more than one patient was brought from the same house; and he found that the later cases invariably corresponded in character with the first one, even where both kinds of fever were prevalent in London at the time. All subsequent writers, whose opinions carry weight, have adopted the doctrine for which Jenner contended, and there no longer remains any doubt about the matter.†

Soon after Jenner's researches were published, Dr Austin Flint, in 1852, showed that the same distinction between typhus and enteric fever was manifest from a comparison of clinical and anatomical facts in the United States, thus confirming the views of Gerhard in Philadelphia, and of Shattuck in Boston.

It has naturally been a point of interest to inquire whether the presence of enteric fever can be recognised in the description given by medical writers in former centuries: and the answer is decidedly in the affirmative.‡ In John Hunter's Museum there still are two preparations showing the characteristic intestinal lesions; and a well-marked case was dissected by Morgagni. It appears, too, that the disease is identical with the "slow, nervous fever" which Gilchrist, of Dumfries, described in 1734, and which Huxham, in 1738, distinguished from "putrid malignant" fever. In works of a still earlier date it must probably be looked for among the "remittent fevers," attributed to the same cause as that of ague. The mistake of confounding enteric fever with malarial fevers was commonly committed in the marshy districts of England up to a very recent period; and in India they are even now separated with difficulty. These facts would in themselves suggest that in former times, when the marsh-miasm was much more widely spread than at present, the distinction would fail to be recognised; and instances in point are probably to be found in the writings of Baglivi (1696) and Lancisi (1718), who recorded cases of fever at Rome in which the intestines were ulcerated, but which they identified with the "hemitritæus," *i. e.* semitertian, a form of ague mentioned by Galen.

Even at the present time a supposed compound disease, due to both malarial and typhoid poison, is generally recognised in America, and by some physicians in India, and has been named typho-malarial fever.

* Dr Stewart, from his comparison of the fever seen in the wards and deadhouse at Glasgow with that seen in the wards and deadhouses of Paris (1836—1839), concluded that the differences between the two diseases were "so marked as to defy misconception, and to enable the observer to form with the utmost precision the diagnosis of the nature of the disease and the lesions to be revealed by dissection."

† Dr Wilks ('Guy's Hosp. Rep.,' 1855 and 1856), Dr Peacock ('Med. Times and Gaz.,' xiii, 1856), Sir Thomas Watson ('Lectures,' 4th ed., 1857), and Dr Murchison ('Continued Fevers of Great Britain,' 1862), were among the earliest who adopted Jenner's conclusion.

‡ An interesting example of the possibility of interpreting historical records by the light of modern science is afforded by an admirable essay in which Dr Norman Moore has satisfactorily proved, from the memoranda of Dr Mayerne, physician to James I, that the disease of which Henry, Prince of Wales, died in 1612, was enteric fever.

Enteric fever is endemic in all parts of Europe and Asia, in the United States, and in Australia. It is common in the tropics, and, though less prevalent, is far from infrequent in Scotland, Norway, and Iceland. In fact, it may be called pandemic in its distribution.

It is doubtful whether enteric fever occurs in more or less modified forms in any species of animal. Mr Bland Sutton communicated to the Pathological Society ('Trans.,' 1885 and 1889) a paper on the occurrence of a disease in monkeys and in beavers, which on anatomical grounds he identified with the typhoid fever of man. The symptoms observed during life were diarrhœa and hæmorrhage. He quoted M. Serres, who recorded an epidemic of what he regarded as enteric fever among the monkeys in the Musée d'Histoire Naturelle in Paris; the symptoms observed were diarrhœa, increased frequency of pulse, and fever, ending almost always in death.

Nomenclature.—Louis' name of "typhoid fever" is an unfortunate term, since the object in giving a title to a disease really distinct from typhus, but liable to be mistaken for it, is to mark the difference between them, rather than the resemblance. Moreover, the same word has long been fitly used to designate a group of symptoms, consisting of stupor with muttering delirium and a dry, brown tongue, which are really *typhoid*, since they are like what is seen in typhus. The two meanings lead to much confusion. The term *enteric fever* or *Enterica* (sc. *febris*) appears to be very suitably substituted, as indicating the fact that the disease is attended with intestinal lesions—though not always with intestinal symptoms.* It has been adopted in the 'Nomenclature of Diseases,' published by the Royal College of Physicians, and is ordered to be used in the official returns made to the Registrar-General.

Incubation.—This period appears to vary within somewhat wide limits. The date at which a patient receives the poison can seldom be directly fixed. At Guildford, in 1867, an epidemic was traced to the fact that contaminated water was supplied on a single day, the 17th of August; a large number of cases came under medical observation on the 3rd and the 4th of September, so that, allowance being made for the gradual development of the symptoms, the incubation probably lasted twelve or fourteen days. On the other hand, instances are recorded in which the disease has broken out within four or five days after the patient has been exposed to sewer gas, or after drinking contaminated milk, or arriving in an infected locality. With regard to cases of apparently much longer incubation there is great theoretical difficulty. Persons sometimes have not fallen ill until three weeks or longer after leaving a place in which there is reason to believe that they must have taken the fever; but the question is at what date the intestinal lesions began to develop themselves in such cases. It has been conjectured that the incubation is shorter when the poison is inhaled with the breath, longer when it is swallowed in drinking-water.

Course.—The beginning of enteric fever is generally slow and insidious. The patient feels depressed and weary, more and more so every day; he has headache, and giddiness, and pains in his back and limbs; he loses appetite, and sometimes vomits. Diarrhœa comes on of itself; or, if he takes an aperient, his bowels remain relaxed. After five or six days he becomes so ill that he

* Murchison proposed as an alternative name, "pythogenic fever;" but this was never accepted, and it involves an erroneous ætiological theory.

has to give up work and take to his bed. In such a case the duration of his illness must be reckoned from the day on which he first felt ailing. There are, however, some cases in which marked symptoms set in with chilliness, or even a rigor, so that medical assistance is at once sent for. If, then, on inquiry, it appears that the patient has been unwell for a few days previously, the disease is said to have had a *prodromal stage*. It is clear that we ought to count the whole duration of such cases; for the lesions are often found after death to be further advanced than had been expected from the clinical history. It may even happen that malaise and other slight symptoms run on for two or three weeks, or longer still, and that afterwards a definite illness begins, the subsequent course of which is not shorter than usual. These instances create a difficulty from which the late Dr Irvine proposed to escape by assuming that the definite attack is in reality a relapse, and preceded by an almost latent primary fever. In every case of this kind, when the patient was ailing before he fell seriously ill, one must be prepared in case of death to find some of Peyer's patches in a state corresponding with an advanced stage of the disease. But it is probable that some of these cases begin as ordinary diarrhœa, and that the disordered state of the bowels renders them more obnoxious to the specific contagion.

In some very exceptional cases, enteric fever sets in with sudden maniacal delirium, so that the patient's removal to a lunatic asylum may appear to be necessary until the real nature of his case is manifested.

According to Wunderlich, the *temperature* during the first three or four days rises in a zigzag fashion: from morning to evening there is an ascent of about 3° F., from evening to morning a fall of about 1°; so that each evening the thermometer stands at about 2° higher than on the evening before; and he declared this course to be in itself diagnostic; enteric fever might generally be excluded if the temperature rose during the first two days to 104°; if (at least in a patient under middle age) it did not rise between the fourth and the sixth day to 103·1°; if it stood at the same level on two successive mornings or on two successive evenings; or if it was ever lower than at the same hour on the previous day. He admitted, indeed, that this stage of the disease comparatively seldom comes under medical observation, but he seems to have overlooked the fact that the exceptional cases in which its onset is marked by definite symptoms are almost the only ones in which the thermometer is likely to be used during the first few days, so that they afford no proof that similar results would be obtained in cases that begin in the usual insidious manner. Jenner remarked to the Clinical Society in 1875 that in private practice there were found to be numerous exceptions to one of Wunderlich's rules, and this certainly accords with the writer's more limited experience in the matter. In 1879 a patient in Guy's Hospital, convalescent from pleuritic effusion, was attacked with enteric fever. He first felt unwell on April 2nd, and his temperature immediately rose from 98·6° to 102·6°; next day he had rigors, on April 4th there were characteristic stools, on April 8th rose-spots appeared. In 1878 a girl was admitted who had been carefully watched from the third day of her illness by Dr Ingoldby; the morning and evening temperatures were on that day 103·4° and 105·2° respectively, on the fourth day they were 103·4° and 104·2°, on the fifth day 103·4° and 102·3°, on the sixth 103·5° and 104·2°.

As the disease advances, the patient's state becomes gradually more and

more serious. He grows weaker from day to day, his mental faculties are more obscured, and he manifests less concern about his own condition. Yet the maximum temperature to be attained in the whole course of the fever is often registered by the fourth, the sixth, or the eighth evening. From that time the thermometer indicates only trifling variations during the next ten or fourteen days, and in the morning it generally stands one or two degrees lower than in the evening. The skin may either be dry or moist. Profuse sweats are by no means infrequent, especially at night; and are sometimes accompanied by an abundant eruption of sudamina, especially towards the end of the second and in the third week, and this again leads to desquamation of the cuticle of the chest and abdomen, the importance of which lies in the fact that its cause may be misunderstood.

The *pulse* is not always very rapid; its beats are generally from 100 to 110 a minute, but sometimes they remain at the normal rate, or are even less frequent. Murchison lays stress on the liability to variations in the pulse-rate at different periods of the day, sometimes in correspondence with the fluctuations of the temperature, sometimes independently. Changes of posture also affect it much more than in health; but the most important peculiarity of the pulse is its soft, compressible character, with a dicrotism which may be so marked that an unskilled observer may actually count it at twice the frequency of the heart's beats. These features are well shown by the sphygmograph.

The *breathing* is more rapid than in health. In many cases bronchitis is present from an early period, but otherwise the respirations are not quickened in the same ratio as the pulse until hypostatic congestion begins to set in.

The *aspect* of a patient with enteric fever is in general that of languor and weariness; the face is not dusky nor is the aspect so stupid as in typhus. There is usually pallor, with a circumscribed pink flush on one or both cheeks, especially towards evening or when food or stimulant has been recently given.

The *tongue*, even at first, while it is covered with a white fur, has commonly a bright red tip and edges. In the course of the second week it often becomes clean, and its whole surface may then be of the same vivid colour and smooth, as though it had been glazed. It sometimes remains moist, but in severe cases it gradually becomes very dry; and deep painful transverse fissures often form in it.

Anorexia and thirst are common to this and to almost every other febrile complaint; nor is much stress to be laid upon nausea and vomiting, although they are often complained of at the commencement of the illness.

The *spleen* becomes enlarged in the course of the first week, and by the end of the second week it is often twice its normal size. Sometimes its edge can be felt below the ribs, but in most cases its extent can only be mapped out by percussion. Even this method of detecting enlargement of the spleen often fails, so that as a negative symptom it is of little clinical value. With resonant lungs and a full tumid abdomen, the organ may be many ounces heavier than natural, without there being any appreciable percussion-dulness over it.

Epistaxis is of rather frequent occurrence, especially soon after the commencement of the disease. It has been known to be so profuse as to destroy life.

Exanthem.—At the end of the first week or early in the second there

appears the *rose-rash*, which is the one symptom of enteric fever that is almost if not quite pathognomonic. It is sometimes preceded by a diffused scarlatina-like eruption which comes out two or three days sooner, and when attended with a slight sore-throat this has led to a mistaken diagnosis. The rose-rash itself is generally, of all rashes, the least conspicuous; to an untrained observer it seems absurd to attach significance to the presence of small red spots hardly larger than pin's-heads, the whole number of which may not exceed a dozen. Yet, when well-marked, they are practically conclusive of the presence of enteric fever. No doubt it is often impossible to say of individual papules whether they are true rose-spots or what Murchison terms "ordinary pimples;" but besides their disappearance under pressure, their colour and the absence of the signs of inflammation of a sebaceous gland, we depend upon their short course and the eruption of a new crop of similar spots. The regions in which they are most often looked for are the lower part of the chest and the front and sides of the abdomen; but they also occur on the back, although a careful physician will seldom be curious on this point. In an epidemic among the French troops at Montpellier (1870–71) Dr George Turner observed that in several cases the rose-spots could only be found on the lumbar regions, and Murchison has seen them limited to the back. In exceptional cases they are scattered thickly over the whole of the trunk, and even upon the face and the limbs. The date at which they first appear is usually between the seventh and the twelfth day, sometimes as early as the fifth or sixth day from the commencement of symptoms, sometimes not before the fourteenth. Liebermeister speaks with hesitation as to their ever being absent throughout the whole course of the disease; but it is certain that, in children especially, one fails to observe them in many cases in which careful search is made every day. They can not only be seen but felt, as rounded, smooth, solid papules; their colour, which is pink or rose-red, disappears beneath the pressure of the finger; they never become petechial; after death they are invisible. In some exceptional cases it is said that their summits are vesicular; they appear in successive crops, so that although the duration of the rash as a whole may be from one to three weeks, each individual spot never remains for more than three, four, or five days, sometimes not longer even than twenty-four hours. It has sometimes been noticed that they have come out in large numbers after a warm bath, or that they have first shown themselves on a part that had been reddened by mustard.

Diarrhœa.—The occurrence of diarrhœa is of considerable diagnostic significance. Sometimes, indeed, it is not present at any period of the disease. The proportion of such cases probably varies in different places and in different years; but Murchison, as the result of twelve years' experience, placed it at one fifth. In many other instances the bowels cease to be relaxed when the patient has been ill for a few days, or they first are loose during the third or the fourth week. Louis stated, and subsequent experience has confirmed it, that, as a rule, the severity of enteric fever is proportionate to the urgency and persistence of the diarrhœa. But it is to be observed that there is no necessary relation between the symptom in question and the extent of the peculiar intestinal lesions. It was thought by Addison that diarrhœa was more constantly present when the colon was ulcerated than when the morbid change was confined to the glands of the ileum, and the same fact was observed by the late Mr Busk at the Dreadnought Hospital; but the rule is certainly not without exceptions. The number of the

evacuations is generally about four to six in the twenty-four hours; sometimes much more. The stools have an appearance which has been compared with that of pea-soup, and which, although not uncommon in other intestinal affections, is probably seen in no specific fever but this. Their colour is yellowish, almost like that of yellow ochre. Addison used to lay stress upon their being almost identical with the normal contents of the small intestine, and he supposed that they were hurried on through the colon and rectum, and discharged without having undergone the usual changes there. Albumen is present in considerable quantity in typhoid stools. The reaction is alkaline, and there are numerous crystals of ammonio-magnesian phosphate. Blood may often be recognised microscopically or in the form of small clots, even when the patient has been ill less than a week, so that ulceration is not likely to have begun. Abundant intestinal hæmorrhage is a serious complication, to be afterwards described. In doubtful cases Dr John Harley recommends searching during the third week for fragments of sloughs from Peyer's patches. He advises that the stools should be strained through a net, and that the matters caught upon it should be washed, and then examined by a lens; flocculent shreds may thus be obtained, in which the remains of intestinal follicles can be plainly recognised. In 1873 a man died in Guy's Hospital, who two days before his death passed a slough an inch and a half long, in which muscular fibres were discerned; at the autopsy the corresponding ulcer was found to be two inches in length, and the peritoneum was exposed in its floor.

Another sign of intestinal disturbance is, in some cases, the production on gentle pressure (which must be applied with extreme caution) of a gurgling sound in the right iliac fossa. There may also be more or less tenderness in this region, and the patient may complain of pain there or in other parts of the abdomen.

During the second week of the disease the bowels generally become distended with gas, so that the abdomen assumes a rounded form. Sometimes the distension is extreme. This tympanites or "meteorism" is a grave symptom. Murchison says that the colon is the chief seat of the accumulation, and that the bulging is therefore at the sides rather than in front.

The *urine* is at first scanty and high coloured, and may remain so throughout the whole course of the disease, but after a time it may become copious, pale, and of a low specific gravity. Towards the end of the third week it often contains albumen in small, and sometimes in large, quantity; and in exceptional cases there may be hæmaturia.

Cerebral symptoms are almost absent in some mild cases of enteric fever. In the course of the second week the headache subsides, and the patient may seem to have but little the matter with him. There is, indeed, no doubt that before the thermometer came into use persons were often wrongly allowed, and even persuaded, to leave their beds with the disease still upon them. There is not always much muscular prostration. Murchison says that forty-four out of one hundred patients under his care were always able to sit up, and to get out to the night-chair; but this should never be allowed, however apparently mild the attack.

In the third week, however, in most cases, and in many much earlier, the patient becomes altogether helpless, and lies upon his back, unable even to turn over. His hands and tongue are tremulous, and occasionally he cannot even put out his tongue. Jenner believes that a disproportionate intensity of *tremor*, as compared with other nervous symptoms, is of signifi-

cance, pointing to the presence of deep ulceration of the intestine, such as is likely to lead to grave perforation or to dangerous hæmorrhage; and Murchison was of the same opinion. In some rare cases the limbs or the trunk become rigid, or the back of the neck is retracted, or there is strabismus, or spasm of the pharynx, or trismus. Murchison's large experience yielded him only six cases of enterica complicated by epileptiform convulsions.

There may be all degrees of *delirium* in this disease, from the slightest rambling or moaning during sleep up to the most violent maniacal excitement, under which the patient screams and shouts for hours together. Liebermeister remarks that one may sometimes fail to appreciate the extent to which the mental powers are enfeebled; a man may answer questions as to his actual condition clearly, but when asked how long he has been ill, what is the day of the week, what the month, what the year, he may be altogether unable to reply. Active noisy delirium (which is more common in enteric fever than in typhus) is always a dangerous symptom. A condition resembling delirium tremens is comparatively infrequent, even in persons who have been intemperate. Sometimes the patient unexpectedly jumps out of bed, and may throw himself out of the window; or if not properly watched he may cut his throat, as in a well-known case of suicide at Newmarket which occurred during delirium at a late period of enteric fever. As Gairdner observes, the patient may lie for days perfectly still and quiet, apparently understanding everything that is said or done, but unable to articulate intelligible replies.

The *pupils* in enteric fever are almost always dilated, as Jenner first remarked; but Murchison observes that where there is complete unconsciousness they may be as narrowly contracted as in any case of typhus.

Resolution.—When recovery is to take place the fever sometimes, though very rarely, subsides by crisis. A medical friend of the writer in whom the temperature from morning to evening had been ranging from 101° to 103° with almost absolute regularity, was found, on what was calculated to be about the twentieth evening, to have a temperature of only 101·1°; next morning it was 100°, in the evening 99·3°; on the twenty-second morning it was 98·3°, and for several days afterwards it remained slightly below normal. But the rule is that at some period of the disease, generally towards the end of the third week, the morning temperatures begin to fall, while the evening temperatures rise to the same level as before; so that on the daily chart a series of acute zigzags is formed. After a few days, these become still more exaggerated, there being perhaps a difference of 4° or 6° between the temperatures of a single day; but the absolute height of the evening rise now begins to decline in its turn, so that each day it is about 1·5° or 2° lower than on the previous day; and thus, towards the end of the fourth week, a temperature is reached which is normal or slightly below normal. This *intermittent* type of pyrexia at the termination of the disease is so characteristic that a correct diagnosis has been based upon it alone, in the case of a child about whose earlier symptoms no information was attainable.

Many cases, however, particularly in children, are convalescent several days before the end of the third week; while, on the other hand, there are not a few instances in which the fever runs on for four, five, or even six weeks without any definite change. In a woman who was under treatment

at Guy's Hospital in 1874 the temperature at the expiration of six weeks was still 103·8°, then it fell suddenly, and within two days became normal. It is in such cases that, if death occurs after several weeks' illness, one finds all stages of the lesions in Peyer's patches and solitary glands down to early swelling. There is therefore reason to doubt the statement that fever protracted for more than four weeks is generally due either to some complication or to non-cicatrisation of intestinal ulcers formed in the early period of the disease. Murchison met with several instances in which fresh rose-spots appeared as late as the thirty-fifth day. Some observers think that the right view to take of such cases is to regard them as examples of relapse occurring "intercurrently;" that is, that before the primary attack comes to an end, a second one begins and carries on the fever without apparent break.

During the stage of subsidence of the fever the pulse sometimes remains quick, and the temperature is often subnormal for several days. This is often a period of much suffering to the patient who, as his mind becomes clear, complains more and more of weakness and of prostration and of the impossibility of finding a comfortable posture for his wasted body and limbs. The loss of weight during an attack of enterica is often very considerable, amounting to twenty pounds or even more.

The *convalescence* from enteric fever is slow in comparison with that from typhus, even when its course is uninterrupted by a relapse or any of the various accidents such as will be presently described as complications and sequelæ. Many weeks elapse after the subsidence of the pyrexia before the patient is fit to resume the active duties of life.

We have still to describe (1) cases of enteric fever which run an abortive course or are exceptionally slight, (2) the mode in which death is directly brought about, (3) complications, some of which may indirectly be fatal, (4) sequelæ, and (5) relapses.

Slight and abbreviated cases.—The symptoms of enterica are sometimes from first to last so slight that there is the greatest difficulty in persuading the patient that he is really ill, and in preventing him from going on with his usual work. Such cases are often seen in hospital out-patient practice in the second and third week, and the clumsy but expressive name of *ambulatory typhoid* has been applied to them. Their duration may be as long as that of typical cases, or it may be slightly shorter. In many of them the affected intestinal glands probably subside without breach of surface, but that this is not always the case is shown by the occasional occurrence of perforation. For latent enteric fever is one of the very few causes that may give rise to acute peritonitis without warning, from the floor of a single ulcer giving way.

Again, not a few cases of enteric fever, attended with well-marked symptoms, subside in the course of the third week. Probably the intestinal lesions are comparatively slight, and the swelling of Peyer's patches and solitary glands disappears by absorption without ulceration. But since it is only by the rarest accident that their condition can be verified by an autopsy, it would be unsafe to make this statement absolute, especially as in other forms of the disease there are so many exceptions to the correspondence between clinical symptoms and anatomical lesions.

Cases which terminate before the sixteenth day, however, require special study, because their real nature being overlooked, they are apt to be set

down as examples of "simple febricula," or of a non-specific gastric or intestinal catarrh. Yet it is unquestionable that such cases depend upon infection with the poison of enteric fever, and they often form part of "house-epidemics." Jürgensen, for example, mentions an outbreak near Kiel, in which fourteen out of twenty persons had an abortive form of the disease. Moreover, in addition to malaise, headache, and anorexia, many cases present rose-spots, diarrhœa with characteristic stools, and enlargement of the spleen. The spots are said to appear at an exceptionally early date, sometimes on the second, generally by the fourth or the fifth day. Moreover this abbreviated variety of enteric fever appears to be particularly definite in its onset. In seventy-four of eighty-seven cases collected by Jürgensen it was sudden, and in forty-two it was attended with chilliness or even with a rigor. The temperature generally rises quickly, and it may be 104° by the second or the third day; indeed, Liebermeister says that he has seen cases in which the thermometer rose to 106° in the axilla, and which yet subsided between the fifth and twelfth days. But more frequently in these short cases the temperature does not exceed 102°, 101° or even less. Its subsidence is generally rapid, without presenting the marked zigzags seen in the commoner and more severe form of the disease, and resolution is completed in from one to three days.

Lastly, enteric fever is sometimes not only of short duration, but also of very slight severity. Liebermeister argued that it may be altogether unattended with pyrexia, appearing as a slight non-febrile catarrh of the intestinal canal, but this would be difficult of proof. The slight as well as the abbreviated cases are most often observed among children.

Fatal cases.—The proportion of deaths to recoveries in enteric fever varies in different cities and at different times to some extent, but perhaps less than might have been expected. Murchison speaks of having seen the disease much more fatal in one village than in another a few miles off, and he seems to have been struck by the fact that several members of the same family have sometimes died of it at long intervals and at distant places. It does not appear, however, in malignant outbreaks, such as those of measles and of scarlatina. At the London Fever Hospital the average death-rate from 1848 to 1870 was 17·26 per cent. of all cases admitted, the extreme figures in particular years being 28·42 and 12·82. For purposes of comparison, in estimating the effects of special modes of treatment, it would, however, be necessary to exclude all cases which ended fatally within forty-eight hours of admission; and this would reduce the average death-rate to 15·82 per cent. Statistics from various sources given by Murchison show a range of mortality from 11·37 to 32 per cent. At Basle, the average death-rate from 1843 to 1864 was 27·3 per cent. At Munich for several years before and after 1880 a very low mortality was observed, and ascribed to treatment by baths; but the patients were soldiers, selected healthy young men, under the most favourable circumstances. At Hamburg, according to Senator, the mortality on 937 patients (1874–77) was 7·2 per cent., and on 568 patients after treatment by cold baths was introduced 7·3 per cent. At Berlin, on nearly 13,000 patients of all ages and under various treatment, the mortality was 14·5 per cent.

According to Goltdammer the mortality from enteric fever in the German army is only 10 per cent., in the Austrian 26·8, in the Italian 28·3, and in the French 36·5 (?).

How difficult it is to judge of the normal mortality, uninfluenced by

treatment, even among patients of about the same age, in the same locality, and of the same habits and mode of life, is shown by the following results obtained by Eichhorst in the General Hospital at Zurich in three successive years. In 1884 there was an epidemic of enteric fever, and of 411 patients fifty-six died (13·5 per cent.); in 1885, of 164 patients only seven died (a little over 4 per cent.); and in 1886 there were only 91 cases, of which five were fatal (nearly 5·5 per cent.).

During ten years (1879–88 inclusive) the number of cases of enterica treated in Guy's Hospital was 415; and the number of deaths seventy-two. One of these was from accidental poisoning by morphia, so that the mortality from the disease was 17·1 per cent.—15 per cent. for men, 21 for women.

The causes of death may for convenience of description be divided into two classes: the general effects of the fever, and special complications. These, though often only aiding in the fatal result, not infrequently cut a case short which was running a favourable course. The greater number of deaths are due to failure of the heart's action, particularly in the pulmonary circulation. This leads to congestion of the posterior and lower part of the lungs, the most dependent in the supine posture of fever; and the mere length of enterica as compared with typhus or scarlatina, makes this result more frequent. The hypostatic congestion, or hypostatic pneumonia as it is called, is not ordinary hepatization but a combination of hyperæmia, œdema, and sometimes hæmorrhage, with more or less lobular catarrh and pulmonary collapse.

The weakness of the heart is no doubt aggravated by severe and unchecked diarrhœa or by repeated hæmorrhage from the bowels, in addition to the inability of the patient to take sufficient food, and the direct effects of the febrile process on the muscular tissues. Death by failure of the heart and engorgement of the lungs, somewhat vaguely described as *asthenia*, commonly occurs in the third or fourth week, and occasionally later still.

Sometimes a condition more strictly so named supervenes after the temperature has fallen, and the diarrhœa ceased. There is no evidence of serious obstruction of the lung, either in rapid breathing and cyanosis during life, or in pulmonary congestion after death; but the patient, instead of regaining strength, lies in a state of complete prostration with shallow breathing and fluctuating pulse for hours or even days before death. He may, however, rally from this condition and recover after all, or it may return after apparent improvement.

Death from *syncope*, by sudden failure of the heart, cutting off the supply of blood to the brain and systemic circulation generally, is rare in enteric fever, but would doubtless be frequent if we did not feed our patients with extreme care, and prevent them sitting up in bed until convalescence is established.

Cases are sometimes cut short by *coma* within the first, and more often in the course of the second or by the beginning of the third week. No morbid appearances are discoverable in the brain or in its membranes, except in extremely rare cases of meningitis.

Death from hyperpyrexia is a very rare event in enteric fever.

Complications.—In a considerable number of cases death is brought about indirectly, by affections which can only be regarded as complications. They are more numerous and varied than in any other acute specific disease.

Foremost among these come certain *abdominal* affections arising out of the intestinal lesions.

One complication is severe *hæmorrhage* from the bowels. Its frequency is difficult to estimate, because more or less blood may generally be found in the evacuations, if it is looked for from day to day. But Murchison says that in 3·77 per cent. of his cases it occurred to the extent of more than six ounces. As a direct cause of death it was noted seven times (in four men and three women) among 415 cases at Guy's Hospital, according to an analysis made by our present registrar, Dr E. W. Goodall.

The colour of the blood may be either bright red or dark, and it may be fluid or partially clotted; if it has been retained for a time in the intestinal canal it is dark brown like chocolate. When it is passed during the second week, it is due to a general venous oozing from the swollen Peyer's patches—unless indeed the real date of the commencement of the disease should have been earlier than was supposed. But at later periods it often comes from an artery exposed during the separation of the sloughs. We have more than once seen one particular ulcer deeply blood-stained or with a clot attached to its floor; and Jenner, in a similar case, injected water into the superior mesenteric artery, and found that it escaped from one of the ulcers. In other instances, however, after four or six weeks of illness, a number of ulcers are found all equally reddened, or the whole mucous membrane of the last two feet of the ileum intensely congested, soft, and swollen. Probably intestinal hæmorrhage is sometimes an indication of a scorbutic condition; for we have seen it accompanied by epistaxis, and by the appearance of purpuric spots upon the legs.

When the amount of blood lost is large, the patient exhibits the usual symptoms of profuse hæmorrhage, and becomes blanched and cold. The rectal temperature also is suddenly lowered, a point of importance, as it may afford the earliest indication of what has occurred, before any of the blood has been discharged.

Liebermeister has found the part of the bowel which contains the blood dull on percussion. According to him hæmorrhage diminishes the rapidity of the pulse, and is often attended with a marked alleviation of the cerebral symptoms. But these effects are transitory.

Hæmaturia has been observed alone or along with intestinal hæmorrhage, and also epistaxis.

There has been a remarkable difference of opinion with regard to the influence of intestinal hæmorrhage upon the course of the disease. Graves, and after him Trousseau, declared that it was not unfavourable; but probably the real basis of their opinion was the fact that many patients recover, or, in other words, that it is not often directly fatal. For the statistics of Murchison and Liebermeister show conclusively that the mortality among cases in which this complication occurs is far higher than the average death-rate of the disease.

It is possible that the cases in question are altogether of greater severity than average cases, independently of their being attended with hæmorrhage. As Murchison remarks, the deep ulceration which opens an artery is very likely to extend still further; and thus it is well established that hæmorrhage, when it subsides, is often followed after a few days by fatal peritonitis from perforation of the bowel.

A considerable loss of blood must impair the patient's power of resisting the disease, and promote cardiac failure. Murchison says that he has

repeatedly seen patients who had been doing well die unexpectedly of syncope a few hours after copious hæmorrhage. A case in point occurred at Guy's Hospital in 1879; the patient, a child aged six, went on favourably for a week after the hæmorrhage and then suddenly expired. Dr Goodhart found considerable dilatation and some degree of fatty degeneration of the left ventricle of the heart. The change was perhaps only such as is frequent in uncomplicated cases; but the hæmorrhage probably intensified it, and gave to it a special clinical significance.

It is worthy of notice that hæmorrhage seems never to afford the earliest clinical indication of an enteric fever hitherto latent, as is often the case with perforation.

The other chief abdominal complication of enteric fever is *peritonitis*, from *perforation* of the bowel. Its frequency is very great, especially in England. Thus, whereas Liebermeister gives it as the cause of death in 8 per cent. of fatal cases of the disease, Murchison found it present in nearly 20 per cent. of fatal cases, and in no fewer than 3 per cent. of all his cases, including those which ended in recovery. All writers are agreed that it more often occurs in males than in females, and in seventy-three instances observed by Murchison, the proportion was as fifty-one to twenty-two. In the 415 cases analyzed by Dr Goodall, 22 (*i. e.* 5·3 per cent. of the whole number, and about 30 per cent. of the fatal cases) died from perforation, and of these 12 were male and 10 female. The aperture is sometimes exceedingly small and rounded, but in other cases, as Dr Bristowe stated in vol. xi of the 'Pathological Transactions,' it is linear, showing that it was due to laceration; and stress must be laid upon the fact that its occurrence is sometimes directly traceable to disturbance of the bowel during defæcation, by the administration of an enema, in the act of vomiting, or in sitting up to take food; or it may be due to irritation from solid fæcal matters, or to the presence of pent-up gas. Again, in certain cases, the gangrenous process affecting a Peyer's patch extends directly through the whole thickness of the bowel, and then a large slough may drop out, leaving a hole of considerable size. One may even find a number of such holes at different spots. Liebermeister observed that when gas escapes freely into the peritoneum, it allows the liver to fall backwards from the ribs, so that the percussion-note in the right hypochondriac region becomes tympanitic. Sometimes a large quantity of fæcal matter is extravasated, and thus round-worms have been found free in the peritoneal cavity.

The seat of perforation is almost always in the lower end of the ileum within a foot or two of the valve. It is said to be sometimes in the cæcal appendix or in the colon, but no instance of either kind appears to have occurred at Guy's Hospital within the last thirty years.

The date at which this terrible complication is more apt to occur is in the third, fourth, or fifth week of the fever. Cases have been recorded in which it has been as early as the eighth, ninth, eleventh, or twelfth day of the patient's illness, but in all probability the disease was really more advanced. Perforation is often the cause of death when there has been profuse diarrhœa, and all the symptoms well marked; but it is sometimes the first sign that anything is amiss with the patient, when the course of the disease has been altogether latent. So, also, it may occur at a very advanced stage, when two, three, or even four months have elapsed, and this may be the case not only when the fever has been unusually protracted, or when there has been a definite relapse, but even when convalescence

has apparently been established, and when perfectly formed and healthy fæces have been passed. In two instances that have occurred at Guy's Hospital, each at the end of the sixth week, perforation has been distinctly traced to the ingestion of improper food. One patient was seized with pain very soon after eating two raw apples, another while eating watercresses.

The symptoms of perforation are identical with those of a sudden attack of peritonitis from whatever cause, but it is important to note that enteric fever yields a large proportion of cases in which peritonitis begins insidiously, so that it may remain altogether unnoticed. In a case observed in 1864 at Guy's Hospital, the chief sign of an unfavourable turn in the patient's illness was his sudden refusal to take food, after which he died in a few hours. Perforation and consequent peritonitis are often found at a *post-mortem* examination when they had not been suspected.

It has been much discussed whether recovery after this complication is possible. The doubt lies in the difficulty of determining whether there is an actual perforation in any given case of peritonitis; but Liebermeister says he has had four cases of recovery in which the abdominal cavity contained pus, and several instances have been recorded in which, death having occurred from some other cause, a perforation has been found sealed up by adhesions, or at least closed off from the general peritoneal cavity. In other cases a circumscribed abscess has formed, which has discharged itself either externally or into the bowel.

In a case of severe enteric fever which occurred in a boy of ten, who lay for many weeks in Philip Ward, during the winter 1888–9, there were one morning all the signs of perforation,—sudden pain, meteorismus, and collapse, with thready pulse and sighing respiration, and extreme local tenderness. A hopeless prognosis was given, but he was treated by laudanum and frequent small doses of brandy, and very gradually the symptoms improved, until he completely rallied, and finally made an excellent recovery.

Acute peritonitis does not invariably start from an intestinal ulcer. Occasionally the mere spreading of a putrid inflammation to the serous surface may light up peritonitis without any actual perforation taking place. It may be set up by sloughing of a swollen mesenteric gland, as in a case recorded by Jenner, in which recovery took place, so that the real nature of the complication would not have been known if the patient had not afterwards died of erysipelas. It has also sometimes been due to extension from an inflamed and ulcerated gall-bladder, or from a suppurating embolus in the spleen.

Such embolic masses in the spleen are not infrequently found after death from enteric fever. They are doubtless the result of plugging of branches of the splenic artery with portions of clot that had formed in the almost stagnant blood in the dilated left cavities of the heart. In the same way embolism of one of the cerebral arteries, causing hemiplegia, with or without aphasia, may arise either during the course of the disease, or later when convalescence has already occurred.

Other complications of enteric fever have their seat in the respiratory organs. A certain degree of *bronchitis* is almost always present, but sometimes it becomes so severe as to constitute a very important part of the disease. Apart from the hypostatic broncho-pneumonia already mentioned as a frequent occurrence, lobar *pneumonia* with true hepatisation, is far more

common than in typhus, and sometimes passes on to gangrene. Pleurisy, too, is often seen, and may lead to empyema.

Ulceration of the *larynx* is present in a considerable number of cases, but it seldom or never produces symptoms during life, and will therefore be described among the anatomical lesions found after death.

Another complication of enteric fever is *parotitis*. This, however, is much less frequent than in typhus. It sometimes affects one side, sometimes both. It may either subside after a week or two, or it may lead to suppuration, with extensive brawny induration and purulent infiltration of the side of the neck as far as the sterno-mastoid muscle.

The occurrence of enteric fever often leads to the reopening of fistulous openings which had healed up, with consequent *necrosis* of extensive portions of bone. Apart from previous disease, periostitis is not an uncommon sequel: according to Paget it most frequently affects the tibia, next the femur, and then the ulna and cranium. In patients who have been suffering from soft chancres he has seen wide-spreading gangrene under the influence of an attack of fever. In two cases at Guy's Hospital an ordinary gonorrhœa has led to sloughing of the penis or of the scrotum under similar circumstances.

As already remarked, in some very rare cases *meningitis* is believed to occur as a complication of enteric fever.

Lastly, we have repeatedly observed renal complications of enteric fever which do not seem to be common, but which have more than once led to a fatal result, and are therefore of practical importance.

Among our 415 cases of the past ten years, two (both in women) were fatal from *suppuration of the kidneys*, and two others from the same cause had been previously recorded. In two cases there was cystitis, sometimes perhaps caused by retention of urine, but this condition, with the attendant dangers of catheterism, is less common in women than in men. In one of these cases (November, 1888) we found the bladder and uterus normal; and in another (Philip Ward, May, 1888) there was no retention of urine, no stricture, and no pyelitis.

In two other patients (also women) acute *tubular nephritis* was found after death, and in one of them, who was under the writer's care in August, 1886, this appeared during life to be the fatal complication. In a third case the patient, a boy of fourteen, happened to be the son of one of the women who died from suppurative nephritis in the hospital a week before (November, 1888). Mother and son had come in with typhoid fever, and both died with uræmic symptoms but from different renal lesions, for in the case of the latter there was anasarca and severe diarrhœa, and acute tubal nephritis with catarrhal colitis were found after death.

4. *Sequelæ*.—In certain cases, affections which are described as complications of enteric fever do not begin until the patient is already convalescent. It is therefore impossible to draw a fixed line between them and the sequelæ of the disease, which themselves may set in before it has come to an end. What really justifies the distinction and renders it useful in practice, is that the latter often run on for many weeks, and obviously constitute the sole obstacle to the restoration of health.

This is the case with *bedsores*, which are apt to form over the sacrum and hips unless great care is taken to prevent them, and which sometimes destroy life by exhaustion, or indirectly by setting up pyæmia.

Another sequela is *thrombosis* of the femoral vein, with the attendant liability to pulmonary embolism.

In some cases enteric fever is followed by *marasmus*. Murchison says that there is not always a repugnance to food; the patient may eat well, but what he takes is not assimilated, and slight errors in diet cause flatulence and diarrhœa. Yet the temperature is normal or below normal, and if death occurs, perhaps after many months, nothing can be discovered except an unusually smooth appearance of the mucous membrane of the ileum, and a shrivelled condition of the mesenteric glands.*

Writers generally speak of pulmonary *phthisis* as frequently occurring after enteric fever. But it is a remarkable circumstance that after searching the records of *post-mortem* examinations at Guy's Hospital, Dr Fagge failed to find a single case in point.

Paraplegia has been recorded by Nothnagel and others as an occasional sequela. It is uncertain whether the lesion in these cases is in the cord or in the peripheral nerves.

5. *Relapses.*—The return of the temperature to normal is not necessarily followed by the restoration of the patient's health; enteric fever is apt to relapse. The frequency of such an occurrence seems to differ in different places: at Basle, Liebermeister met with it in 8·6 per cent. of 1743 cases; Murchison says that in the London Fever Hospital it was observed in 3 per cent. of 2591 cases; the figures given by other writers vary from 11 to 1·4 per cent. Among our 415 cases from 1879 to 1888 at Guy's Hospital there were 46 relapses, *i. e.* about 11 per cent. As a rule, there is an interval of some days between the termination of the first and the beginning of the second attack. Murchison states it as eleven days on an average; Liebermeister found that among 111 cases it was less than four days in twenty-seven, from five to seven days in seventeen, from eight to fourteen days in thirty-five, and still longer in thirty-two. The late Dr Irvine, however, in a valuable paper in the 'Medical Times and Gazette' for 1879, maintained that the average interval is not longer than five days. He believed that a relapse sometimes begins before the original illness has come to an end. As already remarked, this may explain those cases in which enteric fever seems to run on indefinitely for six or seven weeks or longer. It is not very uncommon for the termination of a relapse to be followed after a second interval by a second relapse, and this, again, may be succeeded by a third, and even by a fourth. There is scarcely a more important use of the thermometer in clinical practice than in the detection of such secondary attacks of fever. For it sometimes happens that the patient is unaware that anything is amiss with him, and yet to allow him to get about and to return to ordinary diet is to expose him to fearful risk. Thus at Guy's Hospital in 1876, a man was apparently going on favourably through convalescence, when on the twenty-ninth day his temperature was found to be 104·2°; he looked ill, though he declared that he did not feel so; and a few days later he died of perforation of the intestine. In other instances the thermometer indicates but a very moderate degree of fever, ranging from 100° to 101° or 102°, but nevertheless taking

* When diarrhœa has persisted after the subsidence of the fever, it has been supposed that the ulcers have remained unhealed, or (to employ the usual phrase) have passed into an "atonic" condition. But although Murchison supports this statement with the weight of his authority, I am not sure whether it rests on strict pathological evidence; Dr Wilks long ago taught me to doubt its accuracy, and I have never myself met with any example of it. I remember one case in which a patient was admitted into Guy's Hospital, whose sole complaint was pain in the right iliac fossa, which appeared to have been left behind by an attack of enteric fever; after a few weeks this pain subsided.—C. H. F.

a perfectly typical course. Dr Irvine suggested that when a relapse has been supposed to occur many weeks after convalescence, there have really been one or more intervening attacks which escaped notice. The duration of a relapse is by most writers said to be shorter than that of the original attack. Murchison found it to be on an average sixteen days. Dr Irvine, however, maintained that it is typically twenty or twenty-one days. Cases in which it appears to be longer he explained by the hypothesis of an intercurrent second relapse, interrupting the middle of the first relapse, and subsequently running a regular course. According to this observer the temperature in a relapse generally rises pretty steadily, until on the fifth day it attains its maximum; it remains high until the ninth or the tenth day, when it undergoes a marked fall of from 2° to 6°; directly afterwards, however, it rises again, but it henceforth shows daily remissions, which at length bring it to an end.

It is now well ascertained that relapses of enteric fever are attended with a renewal of the intestinal lesions, although Trousseau maintained the contrary. We have had at least nine cases fatal during relapse at Guy's Hospital within the last twenty-two years, and in every one of them recent morbid changes have been found. As a rule, some Peyer's patches are in a state of early swelling, or have partly formed sloughs, while others show clean ulcers or cicatrices; but in one instance the floors of the patches are said to have been smooth and bare, while their edges showed the pink tumefaction of commencing disease.

The symptoms of a relapse do not differ from those of a primary attack. Rose-spots are said by Murchison to appear somewhat earlier; in twenty-two out of thirty-eight cases they were visible on the third, the fourth, or the fifth day. In all of Dr Irvine's cases the stools were characteristic in appearance. The patient is often delirious and insensible; and, considering the weakness resulting from his first illness, one is surprised that he does not more often succumb. As a fact, however, relapses are seldom fatal, except by some complication, such as perforation, from which recovery is practically impossible. The only one of 46 relapses which ended ill during ten years at Guy's Hospital was one of perforation.

The cause of the liability of enteric fever to relapse is still imperfectly understood. It cannot be due to a fresh infection with the specific poison from without, for the patient is often in a hospital, far removed from the original source of his disease, and little exposed to other infection.

Very often the time at which he falls ill for the second time is when he has just begun to take solid food, or when he has once or twice been out of bed. But other instances cannot possibly be thus accounted for; and at the best, such an apparent exciting cause can only be regarded as setting up the symptoms of a morbid process which would otherwise have remained latent; since, if the patient happens to die a few days later, the intestinal lesions are found to be so far advanced that they clearly must have begun before the obvious relapse set in. For instance, in 1876, a case ended fatally on the sixth day of relapse, and several of the Peyer's patches had already ochrey yellow centres. Such cases probably afford the key to the whole question. In August, 1861, a man was admitted into Guy's Hospital with bronchitis and emphysema. A month later he was attacked with enteric fever, which ran a regular course and from which he recovered, so as to be able to sit up. But early in October the weather became very cold, whereupon his bronchitic symptoms underwent rapid aggravation, and

in a few days they proved fatal. At the autopsy, the lower Peyer's patches were found to be roughened and flocculent, as if sloughs had separated from them; but high up in the ileum one or two patches were still somewhat raised, and several solitary follicles showed an early stage of the affection. This case seems to prove that after an attack of enteric fever has to all appearance passed off, intestinal lesions may smoulder on without giving rise to any symptoms.

Dr Maclagan some years ago suggested that sloughs thrown off from the patches first diseased might perhaps infect other patches in their turn. Such a hypothesis is difficult either to prove or to disprove. But with the analogy of spirillum fever to guide us, we may suppose that the relapse of enteric fever is due to a reinfection of the blood with a virus (doubtless consisting of specific organisms) derived from patches thus recently diseased.

Protection.—Notwithstanding the phenomena of relapse, there is a marked immunity from a second attack of the disease among those who have once finally recovered. In our 415 cases there was only one of a second attack, and that happened five months after the first: after death, from perforation, beside the recent ulcers healed scars were seen in the ileum.

Murchison quotes an observation made by Gendron and Piedvache, that after an interval of many years a particular house or locality became for the second time the seat of an outbreak, whereupon it spared those who had previously suffered, but attacked almost everyone else. Murchison, however, had himself met with several exceptions to this rule, and he cites others.

Diagnosis.—The diagnosis of enteric fever may either be easy or difficult. In some cases a single examination of the patient may enable one to speak positively of the nature of his illness, especially in the second or third week; in some others the most careful clinical observation, from day to day, may leave one to the last in a state of doubt.

At its commencement the disease can never be determined with certainty, although strong suspicions may be excited if there have been other cases in the same house, or the same neighbourhood. In the absence of other cases, the most common mistake is to call the illness a "bilious attack;" and great harm is often done by the aperient dose which follows. The known fact that the onset of enteric fever is generally insidious is apt, when it begins suddenly, to suggest the idea that the case is rather one of typhus, of some exanthem, or of influenza. Liebermeister lays stress on the rarity of nasal catarrh and of sneezing at the beginning of enterica; and another point is that it is very seldom attended with herpes of the lips. As already mentioned, cases of enteric fever have been at first set down to mania.

The occasional early roseola should never be mistaken for scarlet fever, for it does not appear until the fourth or fifth day. Murchison has known a copious eruption of rose-spots attributed to smallpox, in spite of their late appearance and very different distribution.

The mulberry rash of *typhus*, with its petechiæ, its dull diffused mottling, its earlier advent, and its much wider and more abundant distribution, is so different from the scanty crops of rose-spots on the clear skin of the tumid abdomen, that since the distinction between typhus and enteric fever was established mistakes between them are very rare. It must, however, be remembered that typhus is sometimes accompanied by diarrhœa and enterica by constipation. Even where no rose-spots appear one can often feel confident

of the nature of the disease from the course of the pyrexia, the presence of an enlarged spleen, and the characteristic appearance of the stools. But in most cases one's opinion is in reality mainly founded upon negative considerations, and, as Liebermeister remarks, he who is most sensible of his liability to errors is least likely to commit them.

About the end of the first week (that is, within two or three days of the time when the case generally comes under medical observation) a positive diagnosis can, as a rule, be given.

The diseases which are liable to be confused with enteric fever without eruption, or before it has appeared, or when it has been overlooked, may be divided into two groups.

First come certain general diseases. Of these the most important in many countries, although not in England, is *ague*. In India and many parts of America the difficulty of distinguishing the remittent forms of marsh-poisoning from enteric fever, whether in individual cases or throughout a district, is so great that, unless opportunities should arise for making autopsies, mistakes seem almost inevitable, and probably this has led to the hypothesis of a "mixed" form of "typho-malarious fever."

In this country the most important disease simulating enteric fever is *general miliary tuberculosis*, without marked symptoms indicating localisation in any particular organ. But although it is quite true that at an early period of a case it is often impossible to say whether a patient is entering upon one or the other of these diseases, yet our *post-mortem* records at Guy's Hospital show very few, if any, fatal cases in which a correct diagnosis has not been made. It has recently been the writer's fate to supply this deficiency. A boy was ill of enteric fever, which was without diarrhœa or rash, and accompanied by severe broncho-pneumonia. It ran a protracted course, with cyanosis and high irregular temperature, and we regarded it as tuberculosis, and not enterica, up to the time of death. A most remarkable instance of persistent obscurity is recorded by Senator in the 'Berlin. klin. Wochenschrift' for 1881. A man, aged forty-two, was admitted into hospital on October 25th, 1880. He had not been quite well since the beginning of September, but his illness had been more marked for about ten days before his admission. His pulse was 80 to 84. His temperature was 100·4°, and for some days it ranged from 101° in the morning to 103° in the evening very regularly. On October 29th the spleen was found to be enlarged, and on October 31st distinct rose-spots appeared, and fresh ones again on the following day. On November 1st and 2nd there was repeated epistaxis. The pulse, still 80 to the minute, was now plainly dicrotic. Signs of bronchial catarrh appeared, and increased greatly up to November 11th. The bowels were open without diarrhœa. On November 21st suppuration of the left parotid occurred, with discharge of pus through Steno's duct. The diagnosis, about which up to this time there had been slight doubts, was now finally given in favour of enteric fever. Yet after the patient's death, which occurred on November 22nd, miliary tubercles were found in the lungs and in other organs, while the appearances characteristic of enteric fever were altogether wanting. The ophthalmoscope had been used with negative results. A correct diagnosis of this case was surely impossible.

The second general disease that in temperate climates is often mistaken for enteric fever (or the fever for it) or is *pyæmia*, when its starting-point is some deep-seated affection, and when it affects, not joints, but internal organs. Murchison saw several cases of pyæmia from caries of the petrous bone, of

which the course was very like that of enteric fever. At Guy's Hospital, in two instances at least, this mistake was actually made. In each of them the source of the mischief was latent disease of the lumbar or the dorsal vertebræ, there being secondary abscesses in the lungs and the kidneys, and one in the heart. The variations of temperature are in pyæmia always much greater and not unfrequently touch or fall below the normal, which does not occur in enterica except from severe hæmorrhage or from perforation.

Trichiniasis has often been set down as enteric fever by those who have not seen it before; but with due care this error might probably be avoided.

Again, many local diseases may be overlooked, and their effects attributed to enteric fever, if a positive diagnosis be rashly made in the absence of rose-spots.

Foremost among these is a cerebral affection, *tubercular meningitis*, to be afterwards described. An important point, which has been insisted on by Jenner, is that in enteric fever headache ceases before delirium begins; the two symptoms are not present simultaneously as in meningitis, unless indeed this is actually present as a complication.

Before the clinical thermometer was in use, enteric fever was sometimes mistaken for hysteria; in a diabetic patient it has been set down as diabetic coma; and in one who was the subject of lead-poisoning, uræmia, from granular disease of the kidneys, has been mistaken for enteric fever.

Among thoracic affections, *tuberculosis of the lungs* must especially be borne in mind. Enteric fever is often accompanied with bronchitis; and even when miliary tuberculosis produces marked thoracic symptoms it may be difficult to say whether they are not rather due to this complication of fever. Formerly *acute phthisis*, causing a rapidly spreading consolidation of one or of both lungs, was sometimes mistaken for typhoid fever; and a similar error was even made with regard to *simple pneumonia*, when there was no pain in the chest, nor cough, nor expectoration. Even now, although the routine use of the stethoscope keeps us from overlooking the presence of a pulmonary lesion, we may sometimes be in doubt whether it is the primary disease or merely a complication of fever.

Ulcerative endocarditis has often been mistaken for enteric fever; the discovery of a cardiac murmur should in most cases suffice to prevent this error, but in exceptional cases the heart-sounds remain normal. Moreover, a patient already the subject of valvular disease, might fall sick with pyrexia and enlarged spleen, which might be due to enteric fever or to septic endocarditis. Even the occurrence of hæmaturia or hemiplegia would not be decisive.

Various abdominal affections are liable to be confounded at the bedside with enteric fever. Foremost among them is *tubercular peritonitis*. In the absence of the positive signs of this affection its diagnosis from enteric fever may be impossible. We have had more than one case of which the nature has still remained doubtful after several weeks of illness. Again, two or three instances have also occurred at Guy's Hospital in which *acute diffused inflammation of the colon*, generally of diphtheritic character, has been mistaken for enteric fever, there having been no symptoms of dysentery, so far as could afterwards be ascertained.

Other diseases which have failed to betray their presence during life have been *typhlitis*, *perinephric abscess*, and *abscess of the liver* secondary to ulceration of the colon, or (in another case) to suppuration in the broad

ligament of the uterus, with an opening into the intestine. Of these affections typhlitis is the most likely to be mistaken for enterica.

Finally, it is most important to remember that some patients omit to complain of *affections of the genito-urinary organs* sufficiently severe to cause profound constitutional disturbance, and that others conceal them from mistaken modesty. Sir William Gull used in his lectures to speak of cases of extravasation of urine to which he had been called as to typhoid fever, on account of the stupor, muttering delirium, and a dry brown tongue. Some years ago Dr Fagge was asked to see a girl who had been suffering from febrile symptoms, with a very quick pulse. It was not until she had been sent home that she mentioned to her mother that she had severe pains in micturition. There was then found intense diphtheritic inflammation of the labia, and she narrowly escaped with her life. In these cases, as in tuberculosis, and pyæmia, and septic endocarditis, the condition is "typhoid" and it is "fever," but it is not due to the enteric contagium.

Anatomy.—In typhus and in relapsing fever the "general" or "constitutional" character, which is one of the notes of the whole group of specific fevers, is unmodified by any predilection of the contagion for fixing itself in one part more than another. Blood and lymph, solids and liquids, bones, and viscera, all are alike invaded by the poison, and its effects only differ in accordance with the functions of the several organs.

But in several specific fevers we find, in addition to the universal "intoxication" with the poison, that it fixes itself peculiarly in certain *foci*, as we may call them, where it produces definite local lesions. Thus measles, we shall see, particularly affects the respiratory mucous membranes, and scarlet fever the throat. But nowhere is this localisation of the disease so remarkable as in enteric fever. In fact, so striking and clinically important are the local lesions that it was possible for Broussais and his school to regard them as the primary disease, and the fever as merely a symptomatic result. Probably the "typhoid deposits," as they used to be called, in the intestine, are to be regarded as infective granulomata, produced, like the products of tubercle and leprosy, by the local action of specific bacilli.

The most important lesions of enterica are situated in the lymphatic follicles of the intestine, both agminated and solitary. These first become injected and swollen, so that they project further above the level of the surrounding mucous membrane than is naturally the case, even in children. As a rule they rise to the height of one or two lines only; but in some exceptional cases, according to Hoffmann, they may be three eighths of an inch thick. Louis distinguished *plaques molles* from *plaques dures;* the difference between them is, however, merely one of degree, the hard plates being those in which the change is most rapid and intense. After a few days the redness passes of, and the diseased follicles become pale, so white that they have been compared to a thin layer of a soft medullary growth, and in the early days of morbid anatomy were even described as encephaloid cancer of the bowel. The microscope shows that there is a very abundant formation of new cells, which are considerably larger than leucocytes, have large nuclei, and often exhibit signs of multiplying by fission. These cells, besides distending the lymph-follicles, infiltrate the intervening fibrous septa, and may even spread into the mucous membrane above, and into the interstices of the muscular coat and subserous tissue beneath.*

* I have never seen them forming grey granules on the peritoneal surface, as is

The next occurrence is generally ulceration. This seems sometimes to begin as an abrasion of the surface of the diseased follicles, and gradually to extend through their substance. But much more often the whole of the infiltrated tissue, or at least a large part of it, dies in a mass. It then forms a soft, shreddy, flocculent slough, which is of a bright ochre-yellow colour, apparently from imbibition of bile pigment from fæcal matter. Presently the slough is detached, either entire or in fragments. There is then exposed the floor of an ulcer, in which the transverse muscular fibres are often plainly visible, while the gut is so thinned that it is translucent when held up to the light. The muscular fibres themselves may undergo destruction to a greater or less extent, so as to lay bare the subserous tissue—to the imminent risk of perforation into the peritoneal cavity. The edges of the ulcer are thin, soft, and rounded; and when examined under water they are seen to be slightly undermined. Its form at first corresponds with that of the lymphatic organ in which it took its origin; if in a solitary follicle, it is small and rounded; if in a Peyer's patch, it is usually elongated in the direction of the axis of the intestine. In the latter case, too, its position is always remote from the line of attachment of the mesentery. In these respects, as well as in the characters of their floors and edges, the ulcers of enteric fever differ from tubercular ulcers. At advanced stages of the disease it not seldom happens that they are found to be elongated transversely to the axis of the intestine by secondary ulceration, their form being in fact the reverse of that which generally characterises them. At length their floors become covered with a thin grey layer of granulation-tissue, and they heal by the gradual growth of mucous membrane from their edges towards their centres. At Guy's Hospital five cases are recorded, in which death occurred from some other disease within a few months after recovery from enteric fever; in two of them the patches were of a blackish colour, with slaty margins; but in the others the cicatrices seem to have been white; and in one of them it was only on close examination that a deviation from the normal appearance, consisting in a slight unevenness of surface, could be recognised. There is never any thickening or puckering of the affected tissues after this disease, so that it cannot lead to narrowing of the bowel.

Enteric fever by no means affects all the lymph-follicles of the intestines equally. In a large number of cases the solitary follicles entirely escape; in many others those of the ileum are alone attacked; and when those of the large bowel suffer, it is often only in the cæcum, or in the ascending colon; in a very few instances the morbid change extends even to the rectum. It seems, in fact, to spread from the ilio-cæcal valve as from a starting-point. Precisely the same thing is observed with Peyer's patches; the highest of them are very seldom, if ever, affected. As a rule, the lesion is limited to patches within two or three feet of the valve, and sometimes it does not reach beyond a few inches. In very exceptional instances the agminated patches of Peyer remain unaffected, and the solitary follicles bear the whole brunt of the disease.*

described by Hoffmann. But it is not uncommon for adjacent Peyer's patches to become fused together by an extension of the morbid growth, which thus may affect the whole circumference of the lower part of the ileum for some inches above the valve.—C. H. F.

* This apparent caprice of distribution in different cases cannot but suggest the inquiry whether there may not be some in which no glands suffer at all, so that, if the nature of the disease were otherwise doubtful, the criterion afforded by morbid anatomy would fail. The nearest approach to this, with which I am acquainted, is afforded by a specimen which

The morbid process is almost always farthest advanced in the follicles close to the valve; and very often every stage is present, from clean ulcers below, through ulcers containing scattered shreds of slough, to those in which sloughs have just been formed, and from these, again, to patches which are only swollen and excoriated. Sometimes, indeed, the progression is not perfectly regular, a patch less affected being seen at a lower point than one which is more affected. Most pathologists think that these differences depend upon the fact that the follicles are attacked, not simultaneously, but in succession. Dr Moxon, however, held that the morbid change is of less severity, rather than of later date, in the higher patches. He thought that the greater tendency to destruction of those which lie at the end of the ileum is due to the irritating contact of the intestinal contents, held back upon them by the valve. There can be little doubt, however, that in some of the more protracted cases the glands are affected successively and at considerable intervals of time.

But the swollen patches, instead of sloughing or ulcerating, sometimes entirely subside, as was long ago pointed out by Chomel and Louis. They supposed that the morbid material in the follicles underwent softening, and that they ruptured so as to allow it to escape into the bowel. Hoffmann still says that this occurs, and that the follicles become stained in consequence of a little hæmorrhage, so that the Peyer's patches acquire a dotted appearance, the *état pointillé* of French writers. This condition, which has also been compared to a shaven beard, is not peculiar to enteric fever, nor is it uncommon in those who have died from other causes and at all ages. It would be too arbitrary to assume that there was always an attack of typhoid fever which occurred so long ago as to have been forgotten. However this may be, there seems to be no doubt that subsidence of the swollen glands often takes place in a very different manner, namely, by the cell growth in the follicles disintegrating, and undergoing absorption like an inflammatory exudation.* As a rule absorption is found to have taken place in certain patches only, or even in parts of them, while elsewhere there are sloughs or ulcers. Thus in 1862 Dr Wilks examined a case in which, while the solitary follicles had each a depression in its centre, some patches appeared to be in a state of retrogression, parts of them only being slightly raised and nodular.

It is a matter of some practical importance to determine as accurately as possible the dates at which, reckoning from the beginning of the fever, one may expect to meet with the several stages of the intestinal lesions.

I showed at one of the meetings of the Pathological Society in 1875. The only lesions in the intestine were the following:—"One ill-defined purplish-red patch, of about the size of a shilling, situated a foot above the valve; and a little higher up another patch, presenting similar characters, except that in its centre there was a darker spot the size of a pea, with a breach of surface, visible only when it was examined under water." I think it is by no means unlikely that in mild cases of enteric fever, such as could never prove fatal except by some accident, the intestinal lesions are often very slight, and may possibly in rare cases be altogether absent.—C. H. F.

* Among cases which end in recovery it is perhaps not uncommon for all the patches and all the solitary glands which are affected to take this course, but when death occurs at an advanced stage it very rarely happens that some are not found ulcerated. I have only met with one instance of the kind; the patient died on the twenty-first day, and the patches were found swollen, raised, and reddened, but marked by irregular depressed lines and spaces, so that they had a reticulated appearance. They were not "medullary" in character, as would probably have been the case if the affection had been early; there was no trace of sloughing or ulceration. I preserved the specimen in spirit for the museum, but after a few weeks it showed nothing.—C. H. F.

According to Liebermeister, the first week is occupied by swelling and infiltration of the lymph-glands of the bowel; during the second week they either slough or begin to subside; in the third week any sloughs that may have formed become detached, so that by the twenty-first day all the ulcers have clean floors; during the fourth week they begin to heal, but the process is often not completed until a much later period. This statement is easy to remember, and in many cases it may be true, but it certainly is not so universally applicable as to enable us, from the anatomical appearances in a given case, to state positively the duration of the patient's illness. According to Trousseau the swelling of the intestinal glands does not begin to appear until the fourth or fifth day; according to Chomel and Louis not until the seventh or eighth day; but Bristowe and Hoffmann found them enlarged in cases fatal on the fifth and fourth days respectively; and Murchison relates one instance, that of a girl who died forty-seven hours after being suddenly attacked with vomiting and fever, in which the solitary follicles were of the size of hemp-seeds or split peas, Peyer's patches being also similarly affected. Is it not, however, probable that the disease in that case began earlier than its symptoms? In 1871 a man died in Guy's Hospital, who had been definitely attacked twelve days before his death with shivering and aching pains in his limbs, so that he was obliged to go home, but at the autopsy his intestine contained extensive ulcers, all with clean floors except one, which had a few fragments of slough still adherent to it. Surely the lesion must have been in progress before his illness began.

In fact, one is led to the belief that during the period of incubation the invading bacilli produce a local "infective granuloma," and that this remains latent until they (or their spores) leave the intestinal follicles by the lymphatic channels, and overspread the entire organism in swarms.

On the other hand, it is not uncommon, in cases fatal at the end of six or seven weeks of continuous fever, to find sloughs still adhering to several of the patches, while others are merely swollen and medullary looking. But probably the lesions are there of different dates, and have been developed in successive outbreaks at intervals of a fortnight or longer. In the case of a boy who had been ill for five weeks, and who died in Guy's Hospital on October 26th, 1879, Dr Goodhart describes the glands as fleshy-looking, and as just beginning to ulcerate, so that he would have supposed the disease to be at about the eighth or the ninth day. Doubtless some other glands had been affected from the first but had afterwards subsided.

Another lesion in enteric fever has its seat in the *mesenteric lymph-glands*. This does not appear to be absolutely constant; at least, in our records of autopsies there are two cases, one of them fatal on the seventeenth day, in which the glands are said not to have been enlarged. It may be present at a very early period of the disease; thus, in Hoffmann's case, fatal on the fourth day, the glands were already doubled in size. No doubt it results from absorption by the lacteals of contagion from the affected parts of the intestines, and in many instances the lower glands, corresponding with these parts, are alone attacked; but sometimes the upper mesenteric lymph-glands become also involved, and even (as in a case inspected in 1878) glands in the portal fissure. As a rule, the enlargement is moderate, the diseased glands not being larger than hazel-nuts, but they may be as big as horse-chestnuts. Their substance is white, or grey, or pinkish, with spots

of hæmorrhage. Under the microscope they are found to contain large cells, some of which have two or more nuclei, like those in the intestinal follicles. Suppuration sometimes occurs, or partial sloughing, and under such circumstances a cheesy mass may result if the disease subsides; but caseation, or the deposition of calcareous salts, certainly does form part of the ordinary retrograde process.

The *spleen* is found as a rule enlarged and soft, but there are exceptions to the rule. Even in young subjects who died at the height of the fever, it has been found at Guy's Hospital to weigh only six, five, or even four ounces. Bacilli have been repeatedly found in this organ, and have been referred to the specific pathogenic species. Indeed, one enthusiastic pathologist has proposed to insert a small trocar and cannula into the spleen during life in order to diagnose enteric fever, by finding its bacilli in the drops of splenic blood thus obtained.

The *larynx* is sometimes found ulcerated. Hoffmann observed this in twenty-eight cases out of two hundred and fifty. It has generally been set down among primary lesions of enteric fever, but the absence of a specific cell-growth seems important. Probably the explanation of its occurrence lies in some subtle association in morbid tendencies between the larynx, the lungs, and the intestine, of which we have an example in phthisis. As a rule there is a sharply defined ulcer over the base of one or both of the arytænoid cartilages. This lesion very rarely gives rise to symptoms, but it may cause hoarseness, or aphonia. In some instances, however, the morbid action involves deeper structures, and it may even be attended with necrosis and exfoliation of the cartilage, as in a case inspected in 1879. Hoffmann once saw the cricoid cartilage almost completely denuded. The entrance of air may, under such circumstances, be greatly obstructed. Laryngeal perichondritis by Dittrich has been assigned (in other cases as well as in fever), a mode of origin like that of bedsores. And since, according to Ziemssen, modern antipyretic treatment has much diminished the frequency of laryngitis in enteric fever, it seems fair to conclude that the pyrexia is in some way concerned with them. In another of Hoffmann's cases tracheotomy was rendered necessary by the formation of a polypoid blood-clot, which hung down into the interior of the larynx. Again a laryngeal ulcer may endanger life by eating its way deeply into the connective tissue. In a case that occurred many years ago to Dr Wilks subcutaneous emphysema arose from this cause; the patient was a boy aged twelve. A similar instance, in a girl four years old, has since been recorded by Ziemssen. In his report of this case it is specially stated that the seat of the ulcer, which led down to the necrosed cricoid and arytænoid cartilages, was below the cords, and as the child had had much bronchitis there can be no doubt that the cough had forced air through the ulcer into the connective tissue. In two cases the writer has seen sloughs in the larynx of a bright yellow colour, exactly like that which in the intestine is attributed to the imbibition of bile. In one of them there were two linear ulcers, situated one on each side of the epiglottis, a position which is described by Hoffmann as frequent.

Sometimes a thin pellicle of lymph has been found lining both the interior of the larynx and the epiglottis, and still more rarely, a membranous layer resembling that of diphtheria. Whether the specific poison of diphtheria has then been in operation it is difficult to say, but Murchison relates an instance in which fluids escaped from the nostrils when the patient attempted to swallow them, exactly as in that disease.

Zenker, in 1864, pointed out two kinds of degeneration in the fibres of voluntary *muscles*; some become granular, others undergo conversion into a glassy-looking substance, in which no striæ can be recognised, and which splits up transversely into discs. As he himself remarked, however, the same lesion occurs likewise in other febrile diseases, if sufficiently severe and protracted. It is especially marked in the adductors of the thighs and in the recti of the abdomen. Muscles so affected are said to be sometimes obviously altered in appearance, being of a yellowish-grey colour, but this admits of doubt. They may during life be so much softened that they become extensively lacerated; thus, in 1870, a patient died of enteric fever in Guy's Hospital both of whose recti were torn across, and much blood was extravasated into them and into their sheath; and in another case, in 1866, the inner part of one rectus was found to be not only ruptured, but in a state of suppuration. Hoffmann has shown that similar forms of degeneration occur in the tongue, accounting perhaps for the tremor of its movements.

The *heart* is then found to be soft and pale, and sometimes its right ventricle is dilated, or even its left ventricle. Its muscular fibres are commonly more or less granular, and may have lost their transverse striation. In one instance Hoffmann detected in them the glassy change just described as occurring in the voluntary muscles. Among 159 cases in which he examined the substance of the heart it was more or less altered in 103.

The *lungs* are found in the same state of "hypostatic pneumonia" as was described under Typhus (*supra*, p. 111).

The *liver*, again, has been described by many pathologists as undergoing a diffused change; it is soft, and on section it has a pale or "clayey" look. Under the microscope its cells are seen to be granular and disintegrating.* The *kidneys* are often of a greyish colour, and have their epithelium granular. Perhaps this causes the albuminuria which we have seen to be sometimes present.

Wagner and other German pathologists describe the frequent occurrence of *minute grey nodules*—sometimes visible to the naked eye, sometimes microscopic—in the substance of the liver and of the kidneys. Hoffmann noted their presence in thirty-eight among two hundred and fifty cases. A similar observation was once made at Guy's Hospital by Dr Goodhart, in 1879, in the case of a girl, aged seventeen. If it stood alone, one might of course suppose that acute tuberculosis was accidentally developing itself at the same time, just as occurred in a child who died a few weeks later of scarlatinal nephritis; but against such a view is the fact that the lungs in the case of fever were free.

Hoffmann believed that he detected changes in the *brain*. He describes the nerve-cells in the great basal ganglia as deeply pigmented.

Lastly, he found an enormous overgrowth of cells in the acini of the salivary *glands* and of the pancreas. He says that those structures feel unusually hard and dense.

In cases which recover, all these various lesions are doubtless repaired.

* I doubt whether this can account for jaundice in those very exceptional cases in which it is present. It is worthy of remark that the occurrence in the gall-bladder of a colourless mucus, or of a muco-purulent fluid, after an acute illness, is not to be taken as showing that there has been a deficient secretion of bile in the liver. Probably it only indicates that for several days before death there was no storage of bile, in consequence of the very short intervals at which food was taken.—C. H. F.

The process of regeneration of muscular fibres has been traced, and according to Hoffmann the liver-cells are reproduced by proliferation, of which there is evidence in the great excess of nuclei which these cells contain when death happens to occur at advanced stages of the disease.

Ætiology.—It is now generally admitted, after years of controversy, that Enteric Fever is specific in its origin as well as in its course, *i. e.* that it is always the result of infection from a preceding case of the disease, and that it always "breeds true." The phenomena of contagion and incubation, of pyrexia running a definite course, and of subsequent protection by sterilisation of the organism—all agree with those seen in other specific febrile diseases, and lead by analogy to the belief that here also we have to deal with the effects of invasion, and multiplication of a *contagium vivum*, and probably of a microphyte belonging to the group of schizomycetes. But hitherto the demonstration has not been complete. Various bacilli have been discovered in the intestines of those who have died of Enteric Fever, and have been described by Recklinghausen (1871), Klebs (1880), Klein (1880), Eberth (1883), and Friedländer as the typhoid microbe. But none of these claims satisfied even the preliminary criteria stated above (p. 13). More recently, however, Koch noticed and Gaffky has investigated* the occurrence of what is said to be a distinct rod-like microphyte, short and thick, distinct in its size, form, reactions, and the presence of spores; and this has been identified not only in the characteristic lesions of the ileum but also in the mesenteric glands, in the spleen, and elsewhere in the tissues. It has also been reported as occasionally present in successful cultivations from the urine and the fæces. Its presence in the blood appears to be less easy to demonstrate, but it is reported as occasionally present after death in the portal blood (Gaffky), and during life in that obtained by pricking the rose-papules, in rather more than half the experiments, by Neuhaus, by Rütimeyer, and by Fränkel, and Simmonds (quoted by Eichhorst). Attempts to inoculate various animals with a pure cultivation of this bacillus have hitherto failed.

Conveyance of the disease.—Enteric Fever has sometimes been said to be an *endemic* malady, but although it may prevail in certain districts rather than others, yet its diffusion is not, like that of ague, independent of the intercourse of human beings.

Among the most famous examples of *direct contagion* are those recorded by Dr William Budd, in his well-known paper on the epidemic in and near North Tawton, Devonshire, during the autumn of 1839. Three persons left that village after having taken the fever. Two of them went to Morchard and gave it, one to his two children, the other to a friend, and he again to his two children and to his brother. The third went to Chaffcombe, seven miles off, where ten others were attacked in turn, and two of these carried the disease to fresh places, with the result that several more cases occurred at each of them.

In 1875 Sir William Jenner, in his Presidential Address to the Clinical Society, stated that he had twice known enteric fever contracted by students who diligently took temperatures before the registering thermometer was in use, so that they many times a day put their heads almost into the beds of patients suffering under the disease. In 1871 Dr Collie, of the Homerton Fever Hospital, expressed his belief that certain cases

* 'Mitth. aus. d. k. Gesundheitsamte,' 1881–82, and Syd. Soc. Collected Papers, 1884.

among the attendants at that institution were caused by direct infection, either from the freshly-passed evacuations of patients or from their lungs or skin.

But striking as such occurrences naturally appear to the observer who watches their progress, there are strong grounds for rejecting this interpretation of them. Murchison tells us that during nine years, from 1861 to 1870, cases of enteric fever were treated in the same wards of the London Fever Hospital with various non-specific febrile complaints, to the number of 3555 of the former class, and 5144 of the latter. The same night-chairs were used by both sets of patients, and the employment of disinfectants was exceptional. Yet enteric fever was not contracted by one of those who were under treatment for other diseases. In the 'British Medical Journal' for 1879 Dr Shirley Murphy has brought down to 1878 the experience of this hospital in regard to the occurrence of enteric fever among the nurses and other attendants. During twenty-four years only nineteen persons engaged in the institution were attacked by it. "Of these, ten were in no way connected with the enteric-fever patients or the enteric-fever wards. Of the other nine, one was a laundry-maid, whose duties would bring her into contact with the soiled linen of the patients, but who otherwise was not in contact with them. Of the remaining eight there were special circumstances connected with drainage which would probably account for fever, leaving four for whose attacks there was no explanation given." In this time 5569 patients with enteric fever passed through the wards. Is it conceivable that if the disease were directly infectious there would not have been more numerous instances of its spreading? Murchison cites a few instances in which nurses contracted enteric fever immediately after attending upon patients suffering from it; but the fact is not even presumptive evidence of direct infection if the patient remains in the place where he was attacked. So, again, the circumstance that several inmates of a house are affected in succession proves nothing, unless the first case was introduced from elsewhere.

Dr Budd maintained as early as 1856 that the intestinal discharges of enteric fever were incomparably more contagious than the breath or other excreta of the patient. He drew an analogy between the specific cutaneous eruption and the lesions of the intestinal follicles. This doctrine had been previously taught at Munich by von Gietl, and to express this very relation the word *enanthem* had already been coined in Germany as a correlative to the term *exanthem*. Further, it is now supposed that fresh typhoid stools do not contain the poison which is afterwards developed in them. We shall hereafter see that the same thing is true of cholera; in that disease the "rice-water" discharges are probably innocuous when first voided, and become virulent subsequently. Dr Cayley, in his 'Croonian Lectures' for 1880, expresses his belief that this change may occur within twelve hours; for in the Middlesex Hospital patients have apparently caught enteric fever from using closets in which pans were placed containing stools from other cases set apart for inspection. Probably the development of the poison may occur even in fæcal matters smeared upon linen or sheets, for washerwomen have often been observed to take the disease after washing the clothes and bedding of patients. Biermer, in one of the 'Clinical Lectures' published by Volkmann, says that he has met with several instances of this. Cayley mentions two cases of enterica which attacked patients in the wards of the Middlesex Hospital, and which were traced to dried discharges upon the bedding of a typhoid patient in a neighbouring bed. Murchison relates the case of a woman who brought to her house in Warbstowe, on the Cornish

moors, the bedding of a sister who had died of enteric fever at Cardiff, in Wales. She remained free, but her sister, who was employed in hanging out the clothes, took the disease; and it spread from her as a centre.*

That the contagion of enterica is usually conveyed by the "typhoid stools" and thus by sewage there is every reason to believe. If it be the bacillus, it may germinate and multiply outside the human body, and there is no apparent reason why it should not survive, under favourable conditions, for an indefinite period. What, again, is more likely than that the living organism which produces enteric fever should sometimes remain for years in a dormant state, multiplying itself just enough to escape extinction; and that then, when more favourable conditions supervene, it should suddenly undergo immense development? Such an interpretation alone seems to apply to a fact which Murchison himself adduces; namely, that he has seen single cases of enteric fever arise in the same house again and again at intervals of a year or longer. Thus between 1849 and 1857 six cases were admitted from a certain house into the London Fever Hospital; one in June, 1849, one in October, 1851, one in February, 1854, one in November, 1855, one in November, 1856, one in July, 1857. It is unlikely that the disease was six times generated *de novo* in a single building during eight years, or that its specific poison was six times introduced from without. But if the poison was there all along, it may well have undergone excessive development from time to time when the conditions were especially favourable.

Accepting the evidence that the *contagium vivum* of enterica leaves the body in the stools and is thus conveyed to sewers, the question remains how it gains an entrance into the human body, and this is of great practical moment.

The virus may be transported by the air. Many instances have been recorded in which the disease was caused by exhalations from drains, or sewers, or water-closets, but probably this mode of infection is exceptional.

It may be conveyed by drinking-water. Such is the origin of the small epidemics that frequently occur among the inhabitants of a village, who derive their water-supply directly from one or more surface wells, into which sewage finds its way through a porous soil.

At Wicken Bonant, in Essex, the disease prevailed in 1869, and Dr Buchanan investigated its origin for the Privy Council Office. He found that there was a broad division among the people in regard to the sources from which they obtained their water. One hundred and eighteen persons used private wells, and among them there was only one positive case of fever; eighty-eight drank the water of one well called the "parish well," and no fewer than forty of them were attacked. Now, this well was situated four or five paces distant from a brook-channel which ran through the place. At the upper end of the village the brook always contained water; but lower down the channel was dry during the greater part of the year, the water being carried beneath the surface in a stratum of gravel, to reappear as a stream at the bottom of the village. That there was a direct communi-

* Murchison, although he agreed in teaching that the stools of patients suffering under the disease are at first incapable of propagating it, and become so only when they have undergone a change, supposed that the change in question is not the development of a specific microbe, but a chemical decomposition. He held that it was possible for the intestinal discharges of persons not affected with enteric fever to be decomposed in a precisely similar manner, and so to give rise to the disease *de novo*. Indeed, he proposed the name of *pythogenic fever* ($\pi\acute{\upsilon}\theta o\mu\alpha\iota$=*putresco*) in place of the objectionable term "typhoid fever."

cation between it and the parish well was evident from the fact that in times of flood, when the channel was full, the water in the well ran to a corresponding height and became discoloured. On June 24th the first case of fever occurred in the person of a boy, who lived in a cottage about thirty-five yards above the well. He had much diarrhœa, and his stools were thrown, without being disinfected, into a privy which stood almost on the edge of the channel. At this very time the soil water in the village was falling, after abundant rains which had taken place a month before, and pools of water were to be seen here and there in the channel. A month after the boy's illness the persons who made use of the well began to fall ill with the fever. Can it be doubted that the well-water had become impregnated with the specific poison? Previously, on May 30th, two cases of fever had been imported from London into a house, of which the sewer opened into the brook two hundred and fifty yards above the well.

At Page Green, in the parish of Tottenham, a great many cases of enteric fever occurred in 1864 and 1865. Dr Seaton investigated the matter and found that whereas there was to some houses a supply of water from the works of the Local Board of Health, the occupants of many other houses drank water from shallow surface wells. In three instances, in consequence of the families having removed from the place, he could not learn from which source the drinking-water had been taken, but in all other cases, with the single exception of one child, it was ascertained that those who were attacked had used well-water. Some of them had had the water the Local Board distributed to their houses, but had been in the habit of borrowing water from their neighbours' wells, because it was bright and pleasant, whereas the other was hard, turbid, and red, from rust in the pipes. When, however, the well-waters were analysed by Prof. W. A. Miller, he declared them to be quite unfit for dietetic purposes.

At Terling, in Essex, between the beginning of December, 1867, and the end of February, 1868, there occurred an epidemic of enteric fever, upon which Dr Thorne reported. It was of extraordinary severity: amongst a population of nine hundred persons, at least two hundred and sixty were attacked during the first two months; there were in all forty-one deaths, and so panic-stricken was the village, that it was necessary to discontinue the tolling of the church bell at deaths or funerals. Whether the disease was introduced from elsewhere could not be ascertained, for there had been isolated cases during previous years. But the extension of it was clearly traced to contamination of the drinking-water by sewage. The cottages were supplied, singly or in groups, by shallow surface wells, sunk in a loose and porous gravel. Round about them, but at a higher level, there were numbers of manure-heaps, cesspools, and privies, the ordure from which was often spread out for yards over adjacent fields. During the autumn the water in the wells had been unusually low; doubtless, therefore, the filth had accumulated in the soil; so that it was washed into the wells in very large quantities, when, towards the end of November, a sudden rise of water took place. Among seventy-one persons, living on the outskirts of Terling, who procured their water from ponds, only six cases of fever occurred.

In Caterham, during the fortnight which ended February 2nd, 1879, there occurred forty-seven cases of enteric fever; and, at the same time, no fewer than one hundred and thirty-two cases were observed at Redhill, eight miles distant. In each town the persons attacked were using the water

furnished by the Caterham Waterworks Company, but considerable numbers of persons who derived their supply from other sources escaped altogether. On the other hand, cases occurred at the Earlswood Asylum and in other places which also used the Company's water. Now, this water is drawn from chalk wells more than 500 feet deep, and it had a deservedly high reputation for wholesomeness. Every point in regard to its sources, storage, and distribution was carefully inquired into, but for a long time in vain. At last, however, the attention of Dr Thorne was drawn to the fact that in January, 1879, the Company had been constructing an adit, at a depth of 455 feet from one of their old wells, to a new bore which was then being sunk. A number of men had been employed upon this duty, and one of them, it was found, had been ill and had left work in the course of the month. He was sought out, and on inquiring it appeared clear that he had been suffering from a mild attack of enteric fever, which began on January 5th, and which he had probably acquired at Croydon, where he had spent December 25th and 26th. He had much diarrhœa, the bowels acting at least two or three times during each shift of eight or twelve hours, and in accordance with the usual practice under such circumstances he made use of the buckets by which the excavated chalk was being raised to the surface. He denied that he had ever relieved himself in the adit without waiting for a bucket, but it seems to be almost certain that in some way his fæces passed into the water of the well in which he was working and gave rise to the epidemic. The poison must have been diluted to an extraordinary degree.

At Caius College, Cambridge, a local outbreak of the disease occurred in November, 1873, which was traced by Dr Buchanan, with very strong probability, to a precisely similar origin. Twelve out of fifteen cases in students at the college were among the sixty-three residents in Tree Court, a part of the building which had been erected only four years previously with every care as to sewers, drains, and water-pipes. Now, Tree Court had an independent water supply direct from a high-pressure main. This supply was intended to be constant, but there had in fact been a complete intermission of it on two occasions shortly before the outbreak. After such intermissions the water had been noticed to come in with a rush, like "soda-water," evidently in consequence of its having become mixed with air, which had been sucked up into the pipes. Within the Tree Court buildings there were two water-closets, one in the basement of the porter's lodge, the other on the first floor of one of the staircases. The tap of the lower one, or that over an adjoining sink, if left open during the intermission of water supply from the main, would have allowed water to drain from the whole pipe system of the court; that of the upper one would under such circumstances have permitted of the free entrance of air. This air, however, would have been mixed with sewer-gas from an unventilated sewer in Trinity Street, which, at the very time under consideration, was receiving the excreta of patients ill with fever in other parts of the town. The effect of recharging the pipes with water must necessarily have been to distribute sewer-gas in solution to every part of the building. It was, indeed, positively ascertained that not merely air, but water impregnated with fæcal matter, had been sucked up into the supply-pipe of the upper water-closet, for that pipe was lined with a brownish deposit, containing phosphoric acid and a large proportion of intermixed organic matter.

Dr George Turner, speaking from his experience as an Officer of Health,

remarks :—"In the country amongst the cottagers Typhoid Fever appears to spread almost like Measles or Scarlet Fever. A patient returns home ill from the town, and her relations become infected. This is because usually the supply of linen is short; sheets, &c., when stained by excreta, are not immediately changed, and the air of the dwelling, usually a small one, is polluted; but it is more frequently brought about by a scarcity of washing utensils; the same bucket takes the water which has been used for washing the patient's clothes to the privy or cesspit, and then serves for a fresh supply of water, often of drinking-water. I have seen typhoid spread in a village because the family just infected dipped the bucket which had been used for taking away slop-water into the common dipping well, and thus polluted the whole water supply."

Milk may be contaminated with the enteric contagion.—This is clearly shown by the following remarkable instances.

The first epidemic that was traced to such an origin occurred in Islington in 1870. It was investigated by Dr Ballard. Between July 3rd and September 10th the occupants of sixty-seven houses were attacked, one hundred and sixty-seven individuals, of whom twenty-five died. It was a most remarkable circumstance that the district affected was included in a semicircle, with a radius of a quarter of a mile, drawn immediately on the north side of the line of the North London Railway from a centre almost upon this line. There was no fever in the area contained in the corresponding semicircle south of the railway, which here passes through a cutting. This, of course, at once suggested that human intercourse was in some way concerned in spreading the disease. The right clue was first hit upon by a lady, whose family was attacked; and a little inquiry convinced Dr Ballard that, far-fetched as such an idea had appeared, there was much probability in it. The milk vendor whose milk was suspected had himself fallen a victim to the epidemic, but his father, greatly to his credit, readily consented when applied to to give a list of the customers. It was then found that the dairy supplied one hundred and forty-two families, a very small proportion of those who lived within the semicircle. In no less than seventy among the hundred and forty-two families there had been cases of enteric fever. The way in which the disease picked out the customers of the dairy in particular streets and rows was most striking. In one long road and a street running from it the milkman supplied three families; two of them were affected. In a crescent with twenty-five houses he supplied four families; they were all attacked. In a new neighbourhood, where there were about seventy houses, he supplied four families; three had the disease. In a square with fifty-nine houses he supplied four families; all had it. On the other hand, there were scarcely any cases among those families who had invariably bought their milk from other sources. As might have been expected, women and children were attacked in much larger numbers than men. The source of infection was traced, with much probability, to the water of an underground tank in the cowyard. It was not proved that water from the tank had been used to dilute the milk, but the pails were washed out with it, and some might have been left in by accident.

In the summer of 1873 an outbreak of enteric fever occurred in St Marylebone, and in certain parts of St George's (Hanover Square) and of Paddington. It affected among others the family of Dr Murchison, who quickly became convinced that the only probable mode of introduction of the disease into his house was by the milk supply. This was confirmed by

a minute investigation made by Mr Netten Radcliffe and Mr Power. It was shown that nine tenths of the two hundred and forty-four cases to which the inquiry extended were in households which consumed milk from a particular service of a particular dairy. Certain ramifications of the same milk supply extended to the east end of Regent's Park, to Belsize Park (Hampstead), and to St Anne's (Soho), and in these districts also enteric fever occurred among the consumers. There was a special incidence of the disease upon women and children, and many striking instances are noted in which those members of a family were attacked who were in the habit of drinking milk, while others escaped who did not do so. The milk which appeared to convey the poison was a special kind, sold as "nursery milk," and taken from three or four cows, set apart for the purpose at Chilton Grove Farm, in Buckinghamshire. Now, on the 8th of June the occupier of this farm had died in the fourth week of an attack of enteric fever. His evacuations, instead of being thrown into the common privy, were buried in an ash-heap outside the farm buildings. Subsequently, however, it turned out that this was the very worst thing that could have been done with them. For there was a well close by, the water of which was used for dairy purposes, although not for drinking or cooking, as it had been noticed to have a disagreeable taste. Excavations made for the purpose showed that there had been a line of soakage into the well, along the foundations of a wall, of the filth from a pigsty which formed a pool in immediate proximity to the ash-heap above mentioned. If due intervals are allowed for the gradual penetration of the matters containing the poison of enteric fever through the soil, and for the incubation of the disease, the date at which the outbreak in London began—during the last days of June and the first days of July—corresponds exactly with this theory of its origin.

It is possible that meat may under certain circumstances convey the contagion.—At Kloten, near Zurich, six hundred and sixty-eight persons were attacked in July, 1878, all of whom had partaken of some veal provided for a festival of the choral societies, and derived from various sources, but partly from two diseased calves. A few other outbreaks, also attributed to diseased meat, are referred to by Dr Cayley. It is, however, doubtful whether the lower animals are liable to enteric fever (cf. *supra*, p. 136). The so-called typhoid fever of pigs is an entirely different affection.

Finally, it must not be supposed that it is always, or even generally, possible to trace to their source isolated cases of enteric fever, especially when they occur in large towns like London. Probably there are many chances of infection, from sewer-gas in air, and from impurities in water, which no inquirer, however acute, could trace out. The number of cases admitted into the London Fever Hospital varies from year to year much less than might have been expected. Dr Cayley believes that they are not dependent upon the presence of the contagion of the disease in water taken from the Thames; for although there can be no doubt that the poison frequently passes into the upper part of the river from the towns and villages on its banks, he thinks it is always destroyed by exposure to the air and by other agencies, among which vegetable life is probably one of the most important.

Predisposing causes.—Buhl, of Munich, applied the observations of von Pettenkofer on the relation of the soil-water to cholera to the case of enteric fever; he showed that when the soil-water in that city (as measured by the depth of water in the surface wells) is falling, the number of cases of enteric fever increases; when it is rising, the number of cases diminishes. That the

facts are so is generally admitted, but Buhl's interpretation is inadmissible. It was that the falling of the soil-water enables air to penetrate more deeply into the ground than before, and so brings about changes in the organic matters there which result in the giving off of a pathogenic poison. But this is inconsistent with everything that is known of the way in which enteric fever spreads; and no doubt Liebermeister and Buchanan are right in supposing that the observations on soil-water simply illustrate its communication by means of drinking-water. It must be added that in no other place but Munich has a fixed relation been found between the soil-water and the spread of enteric fever. In the case of particular epidemics, as notably at Terling in 1868, the disease has broken out with great severity precisely when the wells have been high.

It is certain that *climatic influences* affect the prevalence of enteric fever. In the London Fever Hospital there have been far more admissions during dry and hot summers (*e. g.* 1865, 1866, 1868, 1870) than in damp and cold summers (*e. g.* 1860, 1872). Each year there is an increase of the disease during the four autumn months from August to November, while it is less frequent from March to May inclusive. Similar observations have been made in Berlin and in Basle, and there can be no doubt that the cause is the heat of summer on the one hand, and the cold of winter on the other; the effect being, however, not immediate, but retarded by two or three months.*

In Australia, as in the United States, enteric fever is most common in the late autumn and after a hot summer. In Victoria (January being mid-summer) the disease is most prevalent in March and least so in November.†

All such conditions play but a secondary part in the ætiology of the disease; their effect is merely to favour, or to hinder, the operation of its real cause.

Age, &c.—Certain circumstances, however, remain to be stated, which affect the power of individuals to resist the contagion of enteric fever. Chief among these is age. The disease is far more frequent in persons between fifteen and thirty than in those who are either younger or older. Under two years old it is very uncommon, but in 1864 Murchison showed at the Pathological Society the intestines of an infant six months old who had been attacked at the same time with her mother. In the last ten years, ending 1888, we have had in our wards 7 cases of enteric fever in patients between three and five years old, 103 between five and fifteen, 241 between fifteen and thirty, 42 between thirty and forty, and 13 above forty years of age. The youngest patient was three and a half years old, and he recovered; the oldest was fifty-four, and he died.

During childhood the liability to the disease increases from year to year, probably owing to increased exposure to contagion. After the age of twenty the liability begins to decline, after thirty more rapidly, and beyond forty very few cases occur.‡ However, Dr Wilks once found enteric ulcers in

* At Munich, however, the maximum prevalence of enteric fever is in February, much too late for even the deeper layers of the soil to retain the heat of autumn.

† From a table given at a meeting of the Intercolonial Medical Congress on January 11th, 1889, by Dr J. G. Carstairs, of Geelong, Victoria, it appears that in Melbourne the mortality is least in November; it rises in December, to attain a maximum in March; falls very slowly in April and May, and has a sudden decline in June. The hottest month in Melbourne is January, when the mean temperature of the air averages 66·2° F.; so that, as with us, the maximum mortality from typhoid obtains about two months after the hottest season of the year is passed. In Melbourne, too, an excess of summer heat is followed by excessive prevalence of the fever.

‡ The proportion of cases over 40 in the three continued fevers observed at the London

the ileum of an old woman of seventy. Liebermeister gives a tabular statement of the proportion of cases at varying ages at Basle, corrected according to the numbers of persons at the corresponding ages in the population generally. This consideration must not be forgotten, nor yet the fact of protection acquired by having already passed through the disease in youth. But it may be that the atrophy of the lymphatic organs in old age, including those of the ileum, may be an anatomical condition which is unfavourable to the reception and multiplication of the enteric microbe.

There does not appear to be any constant predominance of one sex over the other among patients suffering from enteric fever. Among our 415 patients at Guy's Hospital there were 272 male to 143 female, but this is not a constant ratio. There seems to be a certain degree of immunity among women in pregnancy, after labour, and during lactation.

French writers have stated that students, servants, and foreigners are especially liable to contract this disease when they first come to live in Paris; and Murchison has shown that more than 6 per cent. of the patients admitted into the London Fever Hospital have arrived in London within three months.

Prognosis.—The forecast in enterica depends partly upon the condition of the patient before its invasion, partly upon the symptoms which gradually develop themselves as each case goes on, and partly on early and judicious treatment.

The general prognosis with respect to *age* is, as in typhus and small-pox, most favourable for children above infancy and for young adults; least so for elderly patients. But Murchison's statistics show that the mortality does not vary at different periods of life to the same extent as in typhus; and even in old people it is not much more than twice as high as in young adults. The disease, however, is comparatively rare above forty, and not common under five. Almost all the very slight cases occur in children. At Guy's Hospital the mortality under five was 1 in 7, too small a number to afford a guide. Between five and fifteen it was rather less than 12 per cent., between fifteen and thirty a little more than 16 per cent., between thirty and forty a little more than 26 per cent., and above forty nearly 50 per cent.

Enteric fever is very dangerous in drunkards, in those who are very fat, and in those who are affected with Bright's disease. Murchison believed that the death-rate is not augmented by a state of poverty, and that it is probably greater among the upper classes. In pregnant women abortion or miscarriage almost always occurs; but as a rule the patient recovers.

The prognosis afforded by symptoms is exceedingly liable to be unexpectedly altered by the supervention of some grave complication. So that one cannot too strongly insist that no case, however mild, is altogether free from danger. Apart from complications, the death-rate in young adults is found to be greater in proportion as the maximum temperature—usually an evening temperature—is higher, and by the end of the first week the fever has generally reached its highest point, or nearly so. Still more important are observations on morning temperatures; the more marked the morning

Fever Hospital was as follows. Out of upwards of 3000 cases of typhus, nearly 74 per cent. were under, and more than 26 per cent. over 40; out of 437 cases of relapsing fever the corresponding numbers were 82 and 17·5, and out of 1772 cases of enterica 95 and 5.

remissions the more favourable the case. A considerable fall is a good sign, unless it is due to hæmorrhage or perforation. Fiedler found that the disease proved fatal to more than half of those patients in whom the temperature in the morning reached 105·4°, and to every one, with a single exception, in whom it reached 106·25°.

But individuals differ in the extent to which a continued high temperature is injurious, and the best measures of such difference are afforded by the state of the pulse and by the degree of mental disturbance. Liebermeister put together the cases that had occurred at the Basle Hospital, and shows that, the average mortality being 16 or 17 per cent., no fewer than 40 per cent. of those patients died when the pulse reached 120, and 80 per cent. of those in whom it exceeded 140. He also arranged his cases according to the intensity of the delirium and coma, and corresponding variations were found in the death-rate.

Next to the general severity of the febrile process as shown by the temperature, the pulse, and the nervous system, we have regard to the condition of the *heart* and of the *lungs* in forming a prognosis. A feeble pulse and faint systolic sound, and very rapid breathing with cyanosis, are both grave symptoms.

Severity of the *diarrhœa* is also an unfavourable symptom, and soon tells upon the strength. But some of the cases which are entirely without this symptom are far from favourable, and Sir William Jenner has said that he prefers moderate diarrhœa to constipation in enteric fever. Extreme tympanites has long been justly regarded as a very unfavourable sign.

The significance of *hæmorrhage* has been already discussed: there is no question that large or repeated bleeding from the bowels is a very grave symptom, not only in itself, but as indicating deep ulceration.

Of all symptoms the signs of *perforation* are the gravest.

Treatment.—The first and one of the most important points is that the patient from the very beginning of the fever should be kept at complete rest in bed. Not the least advantage of the habitual use of the thermometer in daily practice is that the discovery of pyrexia in what seems a trifling disorder gives ground for insisting that no work shall be done until the temperature has fallen to the normal level. Men are apt to do themselves irreparable injury by struggling on day after day, even if they do not try to "walk off" their illness, or go away for a change of air and a holiday, when they ought to be lying quietly in bed. The members of our profession show no more judgment than others in this respect; Liebermeister has known medical men go on seeing patients after having themselves noted their temperature at 104° on the previous evening. Sir William Jenner, speaking at Birmingham in 1879, declared ('Lancet,' 1879, ii, p. 715) that some of the worst cases of enteric fever which he had ever seen appeared to owe their gravity to the circumstance that the patient had travelled, after having begun to feel ill, in order to reach his home. He added that he scarcely ever allowed a patient to be removed from the place where he was seized with the disease, if his residence was at a distance.

The sick room should be large and airy, and provided with a fire or with a door opening into another room, so that it can be well ventilated without draughts. The danger of a fever patient catching cold is probably much exaggerated.

Diet.—The food throughout the whole course of the disease should be

entirely liquid. The staple ought to be milk, of which two, three, or four pints may be supplied each day; it should be given in regular portions every two hours, or every hour, or even oftener; as the case goes on it soon becomes necessary to persevere with the feeding systematically throughout the night. If curdled milk is rejected by the stomach, or if it appears undigested in the evacuations, it should be boiled, or lime-water may be added in the proportion of one part in three, or the milk may be diluted with barley water; and if it still disagrees, it should be peptonised with *liquor pancreaticus*, which prevents a curd forming.

Other articles of food which may be allowed are beef-tea, skimmed mutton broth, blancmange (made with isinglass and milk or cream), custard, and calf's-foot jelly. Beef-tea is apt to cause increased diarrhœa. It is therefore well to avoid the routine use of broth or extracts made from beef. Veal-tea and chicken broth are less likely to act on the bowels. When there is no diarrhœa, but constipation, beef-tea is rather indicated than not, and its valuable effect on the heart should not be lost. Jenner advises that some strong essence of vegetables should be added to the broths. He permits a little strained fruit juice to be taken, but does not let his patient suck grapes because of the chance of the seeds slipping down the throat; even particles of the pulp of fruits may cause irritation of the bowel.

Pure water may be taken without stint. Toast and water, or lemonade, or barley water with lemons may be preferred, or red or black currant jelly in water, or strained tamarind tea; but before many days the tongue becomes furred and dry, the patient can taste nothing, and cold water is the most grateful drink. Iced water generally quenches the thirst less. Ice to suck can do no harm, but it often rather aggravates than relieves the parched mouth and throat. Painting the tongue with weak glycerine is a better remedy, and the lips should be well smeared with cold cream or vaseline so as if possible to prevent painful fissures.

Stimulants.—The rules for the administration of alcohol in enteric fever in which most experienced physicians are agreed are as follows. Young and healthy patients may go through well-marked attacks with perfect safety when no stimulants are administered throughout. When, however, the pulse becomes very weak or irregular, when the first sound of the heart becomes faint, or when there is great prostration shown by sinking in bed and sluggish reflex action, by the motions passed unconsciously, the eyes half open, the attention scarcely to be roused—then, whatever the age of the patient, stimulants must not be withheld. Most patients above twenty or twenty-five years of age will need alcohol before the disease has run its course, but even here it is generally better not to begin its administration at once, but to wait for indications in the circulation, the breathing, or the general condition. All cases of fever in patients above forty are grave, and stimulants should be freely given from the first.

When the condition of the circulation, or pulmonary congestion, or general depression of the patient's powers demands alcohol, it should be given every two hours or every hour, sometimes for a short time more frequently still. Children generally take brandy better than any other form of stimulant, diluted and sweetened. Young adults often do better with wine, especially red wine, such as burgundy and port. Elderly patients are sometimes wonderfully benefited by champagne. The egg and brandy mixture of the Pharmacopœia is a valuable medicine, and sometimes taken when other forms of stimulant are refused. Whatever form is found best

suited to the case, it should be given as a medicine, *i. e.* in definite doses and at definite intervals.

Drugs.—Almost all observers are agreed that no method of treatment has yet been discovered by which the course of enteric fever can be shortened, but there is no absurdity in supposing this to be possible. We have good reason to believe that the disease sometimes spontaneously aborts at the end of the second week, and the number of cases in which this occurs may possibly be increased. Liebermeister is disposed to believe that by three or four doses of from eight to ten grains of calomel, given within twenty-four hours at an early period of the fever, he succeeded in certain cases in cutting short the disease, and this treatment is much followed in Germany. Antipyretics, antiseptics, and other remedies are more generally used there than in England, but here also we hear from time to time of new methods of specific treatment, which, as a rule, turn out on trial to be either useless or harmful.

At present the most rational and successful treatment of this, as of most other fevers, is to help the patient by rest, suitable food and good nursing; to watch carefully and intelligently, and to interfere when complications arise but not before.

Treatment of the pyrexia.—Of late years the most disputed question has been whether it is advantageous to keep down the temperature systematically by *cold baths*. A mass of evidence has been accumulated in support of this practice, which had fallen altogether into neglect, although it had been advocated and successfully practised by Currie, of Liverpool, nearly a century ago. The revival of the treatment was due first to Brand, of Stettin, in 1861, and secondly to Jürgensen, of Kiel, in 1866. Since that time it has been widely adopted both in Germany and in England; here no one has studied it more carefully than Dr Cayley, of the London Fever Hospital, who recorded his experience of it in the Croonian Lectures for 1880.

The fundamental proposition upon which the antipyretic method of treating enteric fever is based is that pyrexia is harmful, because the tissues, and particularly the heart, are injured by exposure to a high temperature, especially when it is continuous and protracted. Those who recommend this practice appeal not merely to the vague impressions derived directly from the observation of cases, but to a numerical analysis of the results which they have attained.*

Notwithstanding, however, the weight which the judgment of those who advocate systematic baths in enteric fever justly carries, many are unconvinced of its advantages. Statistics of results are much open to fallacies. Some epidemics are very slight, others very severe. A case early treated and carefully nursed and fed, will do well, when one not seen until the second week will die. The dependence of mortality upon the patient's age is so remarkable that we can only fairly compare those of about the same time of life. The two most formidable complications, hæmorrhage and perforation, may at once change a favourable into a hopeless prognosis. Lastly, there is no acute disease which varies so greatly in symptoms, severity, and reaction to treatment, as enteric fever.

At present, therefore, it seems desirable (in accordance with the experience of Dr Alex. Collie and many other experienced physicians) to employ means of reducing the temperature, not as a routine method of treating the

* See, for example, statistics of mortality in enteric fever, before and after the treatment by baths was introduced, at Berlin, at Hamburg, and in the German army, by Senator, Goltdammer and others, 'London Med. Record,' Dec., 1886, p. 557.

disease, but as a special method of treating the symptom of high fever. It is doubtful whether moderate pyrexia—say under 103° F.—is of itself injurious, and whether its suppression, if possible, is desirable. But there is no doubt that hyperpyrexia is a dangerous condition in itself and should be dealt with energetically. At what point we should interfere cannot be absolutely laid down. A temperature of 104° in a child may be left alone, when one of 103·5° in an adult must be dealt with. A considerable evening rise which subsided well towards morning may be only watched, while pyrexia which rose high last night and scarcely remitted this morning must this afternoon be checked as soon as it begins its ascent. Moreover, the presence of delirium and restlessness, or of a very rapid pulse, shows that *for that patient* the temperature is high and must be treated, although the same or even a higher temperature unaccompanied by grave disturbance of the nervous system and the circulation may be safely left to itself.

When we have decided on bringing down the temperature, there are several ways of accomplishing it. One is to place the patient at once in a cold bath of 60° or 65° F. The shock may sometimes serve as a useful stimulus; but it is almost always better to use a tepid bath of 90° to 85° F. and rapidly cool the water with lumps of ice. The temperature is best watched by means of a thermometer *in recto*, and it must be remembered that it will most likely fall considerably after removal from the bath. Another important precaution is to give brandy immediately after, or even before, the bath, so as to stimulate the heart and further the cutaneous circulation. Currie's original plan of cold affusion is best adapted to relieving headache and delirium with pyrexia by directing a douche upon the head. The practical difficulties of a bath in the case of adult patients, and the serious disadvantage of lifting and moving them, it may be many times in a few hours, speak strongly for applying cold to the surface as they lie in bed. For this purpose the "wet pack" has been often used with good success; it is usually soothing and sedative as well as antipyretic, but is less effectual than the bath, and sometimes is resented. Another plan is placing bladders of ice in the axilla and over the great vessels of the neck and thighs, or fixing a coil of Leiter's tubes in the same regions and feeding them from a receptacle of iced water placed over the patient's bed. But in many, perhaps in most cases, the easiest and safest is also the most efficient method, namely, sponging the surface with cold water, or rubbing the trunk and limbs with pieces of ice, as the patient lies on a blanket with a waterproof sheet under it. Even when there does not appear any call for active interference, sponging the face, arms, and legs, with cold water or spirit lotion, is grateful to the patient, and is often followed by tranquil sleep.

Many *antipyretic drugs* have been recently used in enteric and other fevers, sometimes in conjunction with, sometimes instead of, what may be called 'the cold-water treatment." And certain of these have been credited with antiseptic power in addition, by which the course of the disease apart from the pyrexia is modified. Of these, quinine in large doses was at one time popular, but, except under special circumstances, it cannot be depended on to bring down hyperpyrexia, and is of doubtful value for any other purpose.*

It also is believed in this country that salicyl compounds, invaluable as they are in rheumatic fever, are probably worse than useless in pyrexia from other causes.

* "Large doses of quinine are as useless and injurious as in typhus" was Murchison's verdict.

Kairin (a chinolin compound, the hydrochlorate of ox-ethyl-chinolin hydride) was one of the first artificial antipyretics introduced. It is efficient, but the effect is evanescent, and it depresses cardiac action.

Antipyrin (or antipyrrhin)—belonging to the same chemical series, dimethyl-oxychinicin—is more lasting in its effects, but it also has to be frequently repeated, and is dangerously depressing to the heart. Moreover, it is apt to produce vomiting and sometimes rigors, while collapse may follow full doses.

Thallin (the sulphate or tartrate of tetra-hydro-para-chinanisol) is probably as efficient, or more so, and safer. But it also sometimes produces rigors, and is not entirely free from danger.

Antifebrin (an anilin not a chinolin compound, phenyl-acetamide) is said to be more useful, more agreeable, and more safe than any. It acts more slowly than kairin or antipyrin, but its effects last longer. It is efficient in small doses; but, when repeated, three grains may prove depressing, and ten grains may cause alarming collapse.

One great drawback to all such drugs is the difficulty of knowing when to give them so as to *prevent* the rise of temperature, and another is their accumulative depressing action on the heart.

Apart from special treatment of the pyrexia, or of the particular symptoms to be mentioned immediately, it seems to be grateful to most patients to take what is called "a simple febrifuge," such as ten drops of dilute hydrochloric acid in infusion of orange, of calumba, or of serpentary. It is probably a mere placebo, but there is every reason to please as well as to cure our patients.

Treatment of other complications.—The most fatal of all accidents, *perforation*, can only be relieved by opium when it has once occurred. Treatment consists in preventing it, by checking peristalsis, and by scrupulous care in feeding after as well as during the attack. In one case, however, referred to above, it appeared likely that a patient recovered from this all but fatal accident under laudanum and brandy.

Hæmorrhage should always be regarded as a serious symptom, and arrested, if possible, by gallic acid, by acetate of lead, by ergot, and above all by laudanum, or subcutaneous injection of morphia and ergotine. Turpentine was used by Graves, and is sometimes efficacious, but the great indication is to stop peristalsis by opiates. According to statistics, the practice of systematic cold baths does not appear to favour intestinal hæmorrhage in enteric fever, but the reverse.

In cases which are not cut short by perforation or hæmorrhage, the cause of death is usually *failure of the circulation* with hypostatic congestion of the lungs. Beside the free use of stimulants, as described above, great benefit is derived from the common senega and ammonia mixture, or carbonate of ammonia alone in three- to five-grain doses, with its pungency removed by treacle, syrup of tolu, or liquorice, and, if needful, laudanum or paregoric added to prevent laxative effects. With this digitalis may be given, and sometimes its effect on the rapid, feeble, and irregular pulse is striking and most useful; but often it disappoints us, and on the whole is less to be depended on in these cases than when a similar condition of the pulse is produced by valvular disease of the heart.

Diarrhœa should be checked from the first. If there are not more than two loose motions in the twenty-four hours, if the patient is young, and the fever not severe, we may wait; but as soon as this is exceeded, the

starch and opium enema of the Pharmacopœia should be administered, and repeated after each movement of the bowels. When pain and restlessness are also present, Dover's powder is probably the best form of opiate to give internally, and chalk mixture, catechu, or other astringents are often prescribed with advantage; but in most cases it is better to leave the stomach as much as possible for food and alcohol.

When there is constipation instead of diarrhœa, and especially if there is much flatulence and discomfort, a soap-and-water enema may be administered. Murchison recommends a teaspoonful of castor-oil, and repeats it every three or four days if there is constipation throughout the fever. Knowing, however, that in all cases there is some ulceration of the ileum, and that the degree of diarrhœa is no certain guide to its severity, the writer ventures to think it better to err on the side of caution, and to abstain from meddling with the bowels until convalescence is established. He has frequently seen a patient pass through the disease favourably with constipation throughout; he has twice seen such cases die from perforation, and been thankful that even an enema had not been used; and again and again he has seen the bowels act naturally and comfortably after the temperature had fallen, without aid from drugs.

No qualified man would think of giving ordinary laxatives in a case of enteric fever, but we often meet with cases in which harm has been done by saline and other purgatives being taken for a supposed "bilious attack" before the true nature of the disease has been recognised.

Tympanites is not only an unfavourable symptom but is also injurious. It may be met by turpentine stupes or by enemata containing asafœtida or other carminatives. The distension is chiefly in the colon, and therefore drugs given by the mouth are not of much service.

Bedsores ought to be prevented by extreme cleanliness, by careful drying and dusting after each evacuation, and by daily friction with brandy from the first. When the skin is already red and threatens to break, it is better to apply lead lotion frequently. Careful shifting of the patient so as to vary the points of contact as much as possible is part of a skilful nurse's duties. A water-bed is an important preventive.

Treatment during convalescence.—Stimulants should be at once diminished on the subsidence of fever, and in many cases it is desirable to substitute an ounce or two of wine twice or thrice a day for brandy at frequent intervals. With young patients, however, after a favourable attack there is often no need for stimulants or drugs. No solid food should be given for a fortnight after fever and diarrhœa have ceased. The patient will bitterly complain of the restriction, but if the physician has once lost a patient from perforation during convalescence he will be inexorable ever after. Progress to health after this disease must be slow if it is to be sure. Leaving the bed, taking meat, going downstairs and out of doors—each stage of convalescence must be carefully considered. And there is no disease, not even rheumatic fever, in which it is so important for the patient to have a long period to recover his strength before returning to his ordinary duties.

Prophylaxis.—As we have seen, there is little danger of infection being incurred by doctors or nurses in charge of a case of enterica, either because the bacilli in the fæces are not yet become toxic, or because they rarely succeed in gaining entrance except when swallowed in liquids.

Nevertheless it is desirable for the patient's stools to be disinfected, so as, if possible, to prevent contagion being conveyed into drains, and, by want of sanitary precautions, into drinking-water.

For this purpose various methods have been tried. Crude sulphate of iron placed in the bed-pan is cheap and effective; carbolic acid has also been much used, and chloride of zinc and of lime. Dr Foote, of Yale College, U.S.A., has made some careful experiments on the sterilising effects of various antiseptics, and finds that 5 per cent. solution of carbolic acid and 2 per cent. of corrosive sublimate are ineffectual. Fresh chloride of lime he finds, on the whole, the most efficient. Corrosive sublimate with excess of hydrochloric acid is very active, but injures lead pipes.

FEBRICULA.—When continued fever was no longer regarded as one "disease" with endless varieties, and when the distinction between Typhus and Enteric was established, Relapsing Fever formed a third "species," and a fourth was called Simple Continued Fever, Ephemeral Fever, or Febricula.

This was described by Jenner in his well-known Lectures, and admitted by Murchison among the 'Continued Fevers of Great Britain.' But most physicians now believe that a disease without any morbid anatomy, without any known ætiology, and without any definite or characteristic course or symptoms, cannot be admitted into a useful nosology. This was the opinion of the late Dr Tweedie. In some admirable 'Lectures on Fever' delivered by Dr Peacock, of St Thomas's Hospital, he wrote as follows:—"The cases which have been classed under this head embrace a variety of different affections. Some are probably cases of imperfectly developed typhus, typhoid, or eruptive fever; others may be cases of relapsing fever, in which the relapse does not occur; and yet others may depend on common causes—exposure to cold or damp, noxious miasms, or on gastric, intestinal or hepatic disorder. I should rather regard the so-called ephemeral fevers as abortive attacks of one or other of these forms of disease, than as possessing a specific character of their own. You will constantly find that when a series of cases occurs in members of the same family, some are characteristic attacks of typhus or typhoid, while others present only slight febrile symptoms, to which we may apply the term Febricula or Ephemera. Thus, in the three cases of typhus which I have before referred to as examples of contagion and of the varieties in the form of the eruptions on the skin, the first two, those of the patient and the first nurse, were examples of characteristic and severe typhus; the third case, or that of the second nurse affected, was merely a slight febrile attack in which no eruption appeared on the skin. Again, among the typhoid cases is included one which presented the characteristic features of the disease during life, and proved fatal, and after death extensive intestinal disease was found. The brother of this boy was under treatment at the same time, and in his case the fever was only slight; and numerous similar examples might be quoted. We see facts precisely analogous during epidemics of the eruptive fevers, and especially of scarlatina."

This opinion will probably be shared by most scientific physicians. It may have been needful to include in the College of Physicians' Nomenclature (1884) "Simple Continued Fever," with the definition, "Continued Fever, having no obvious distinguishing character;" but if obvious characters for diagnosis fail, we must seek for those which are more latent.

It must, however, be admitted that remarkable cases of fever do occur, which we must at present leave unexplained and without a name.

(1) There are cases of pyrexia and even hyperpyrexia without other signs of fever. Some of them have been referred to already (*supra*, p. 41), which occur in women between the ages of fifteen and forty-five; but others remain. In 1886 there was a patient in Philip Ward, a healthy, decent mechanic, of about forty, who for several weeks suffered (or rather did not apparently suffer) from high temperature, with the normal diurnal variations exaggerated, and sometimes reaching 105·6° F. Yet he ate and slept well, and there was no local lesion to be found. At last the temperature gradually fell, and he went out well. The case was published by Dr Hale White.

(2) Children are apt to be affected by pyrexia, and sometimes by a sharp attack of fever, from causes which in adults would cause only insignificant disturbance. Slight gastric catarrh from eating indigestible food, diarrhœa from eating raw fruit, from chill, or exposure to heat or fatigue, will be enough to cause febricula, and the diminutive will often apply to the duration only, not to the height of the pyrexia. The "infantile remittent fever" of Evanson and Maunsell is probably almost always enterica without the rash.

In young women (who retain the pathology of children much later than youths of the other sex) similar short and sharp fever is not infrequent from "gastro-entérite" due to indigestion or chills, from retention, suppression or disorder of the menses, and particularly from a degree of sore-throat which falls very far short of quinsy.

Here may be mentioned the remarkable cases of gastro-enteritis with fever which are sometimes the result of eating bad meat or fish.

(3) Slight cases of enteric fever have often been called febricula. In the absence of the rash, enlargement of the spleen is probably the best diagnostic sign. See an interesting discussion reported in the 'Dublin Journal of Medical Science' for July, October, and November, 1879, by Drs Cameron, Grimshaw and others, and a valuable paper by Prof. Bäumler of Freiburg-in-Breisgau, on the question, "Can the mildest forms of enteric fever be distinguished from acute febrile but non-specific gastro-enteric catarrh?" (*ibid.* November, 1880). See also Jurgensen's paper in 'Volkmann's Sammlung,' tr. New Syd. Soc.

(4) There remain, however, certain epidemic and probably contagious febrile disorders which cannot as yet be brought under any recognised category; they are neither continued, eruptive, malarious, nor symptomatic. The best observed instance with which the writer is acquainted is detailed with great care and judgment by Dr Seaton in the Clinical Society's 'Transactions' for 1886 (vol. xix, p. 26). No less than 157 cases occurred during the four summer months (June to September) in a boys' orphanage. The attack began suddenly with rigor and severe headache, and the temperature rose rapidly to its maximum, which varied from 101° to 105° or even 106°. There was often severe vomiting, with no diarrhœa, but with scanty urine in which the chlorides were remarkably deficient. In most cases the fever ceased in two or three days, in others on the fifth or sixth, and labial herpes usually appeared at the same time. Earache with otorrhœa and pneumonia were the two complications noticed. Death occurred in seven cases. *Post-mortem* examination threw no light on the disease, but it appears to have been only made in a single case.

MEASLES*

"We bear diseases
Which have their true names only ta'en from beasts,
As the most ulcerous wolf and swinish measle."
WEBSTER.

History and Nomenclature—Ætiology—Incubation—Onset—Course and Eruption—Varieties—Complications—Sequelæ—Protection—Diagnosis—Prognosis—Treatment.

No mention of this common and well-marked disorder is found in the ancient medical writings; but, in the ninth century, the celebrated Arabian physician Rhazes† described Smallpox and Measles in a treatise which was translated into Syriac, Greek, and Latin, and is still extant. Measles was long regarded as a minor form of smallpox.

The name *Morbilli* (Ital. = a little plague, *i. e.* compared to Variola) seems to have been constantly used until the middle of the eighteenth century, when Sauvages invented the term *Rubeola* (the red rash, from *ruber*). This name was unfortunately adopted in Great Britain by Cullen and by Willan; and their authority led to its general acceptance. But within the last few years most English writers have reverted to the use of the term *morbilli*. The English word measles means spots, as in the phrase "measly pork."

Origin and propagation.—Measles is a strictly contagious, specific, febrile disorder, and has been propagated over temperate, warm and cold climates, so that it is now almost pandemic. Its introduction into Iceland, the Faröe Islands, and the Fiji Archipelago, took place in recent times. Like smallpox and syphilis, it was much more severe and fatal when thus imported into a virgin soil. Even in England local epidemics may be observed. Sydenham described the prevalence of measles in London in the years 1671 and 1674, and Haslam at Plymouth in 1741.

The contagion, though active and sure, is not persistent, and it is readily dissipated by ventilation. It is probably conveyed by the secretion from the affected mucous membranes, by the breath, and perhaps also by the skin after the rash has appeared.

The contagium has not been isolated, and it is unknown whether it is a microphyte. Messrs Braidwood and Vacher observed minute glistening particles in the mucus of measles which resembled those seen in vaccine lymph ('Path. Trans.,' 1878, vol. xxix, p. 421). Attempts to inoculate it by the blood have failed.

If measles occur among the lower animals, it has not yet been identified.

Measles is a disease of children. Most persons above puberty have already had it; but cases occur at any age, and unprotected adults take it

* *Synonyms.*—Morbilli—Rubeola.—*Fr.* Rougeole, *Germ.* Masern, *Ital.* Rosolia fersa, *Arabic* Hasbah.

† Abubekr Mohammed ar-Razi, born at Rai (whence his surname), a town of Irak Ajemi, in Persia, about 850 A.D.

very readily and as a rule severely. The only predisposing cause for measles that we know is Whooping-cough.

Incubation.—This has been carefully observed in cases which have occurred on board ship, and in the remarkable epidemic which invaded the Faröe Islands in 1846. Panum (afterwards the eminent professor of physiology at Copenhagen) found that a period of thirteen or fourteen days elapsed between exposure and the appearance of the rash, *i. e.* the incubation period was ten or eleven days.

Further exact observations have shown that although variations occur, they are less than in most other cases of contagion, so that the disease rarely manifests itself before the tenth or after the thirteenth day. When designedly inoculated by mucus from nostril to nostril, the period of incubation is shorter, as it is with inoculated variola—eight or nine days.

During this period the child continues apparently in perfect health.

Onset.—The patient is taken suddenly ill with anorexia, headache, and malaise; vomiting may set in, or diarrhœa, or epistaxis, or a rigor, or (in very young children) a convulsive seizure; and by the evening of the first day the temperature has reached 102°, or more. Yet the course of the fever during the next two or three days is uncertain. On the second or the third day the thermometer may fall to normal; and, as the appetite may at the same time return, the idea of an impending illness is often abandoned. In other cases, however, the temperature remains at about 102°, with only slight oscillations.

There are *catarrhal symptoms* from the first; the patient is troubled with coryza, sneezing, intolerance of light; fluid secretion pours from his eyes and nose, his face and eyelids are swollen, and his conjunctivæ are injected. He is sometimes hoarse, coughs, and sibilant or sonorous rhonchi may be audible on auscultation. By the second, or at latest by the third day, one finds on looking at the fauces that besides a general injection of the soft palate, there is an eruption of scattered points and spots over its mucous membrane. Ringer attaches some importance to the presence of thin, opaque, white patches on the gums, and the inside of the lips. In the pharynx one can hardly recognise anything more than a diffused redness, and the same has been observed within the larynx by the aid of the laryngoscope. Some writers have regarded all these appearances as indications of an exanthem of the mucous membrane, and have proposed to term it an "endanthem." This appearance may be of clinical value in enabling measles to be recognised among the dark races of mankind, in whom no cutaneous exanthem is visible. This slight angina is all but constant.

The tongue is coated with white fur, through which a few red papillæ may perhaps be seen projecting. The pulse is less rapid than in scarlet fever. The respirations are but little increased until the advent of bronchitis or pneumonia. The urine not infrequently shows a trace of albumen, or more than a trace, and this does not appear to add to the gravity of the case. The faucial affection and the early catarrhal symptoms in general continue into the eruptive stage and then subside. According to Professor Thomas, of Leipzig, indications of the approaching cutaneous rash may sometimes be seen on the face during the prodromal stage, in the form of minute puncta, around which the characteristic papules afterwards develop.

Course.—The *eruptive* stage which succeeds begins generally on the fourth, but sometimes on the third day of the illness, and from the fourteenth

to the seventeenth from infection. In exceptional cases it is postponed until, according to Trousseau, six, seven, or eight days of fever have elapsed; or even, according to Watson, until the tenth day. There is now a further rise of the temperature, which in thirty-six hours (as a rule, on the sixth day) reaches its acme, this being generally 104° or 105°. Afterwards it may either begin at once to decline, or may remain at or near the same point for a day or two. The fall, when it does occur, is rapid, and the normal temperature is reached often before the end of the week, or by the eighth or the ninth evening at the latest.

Prof. Thomas seems to have studied the thermometric changes in measles with more care than any previous observer; and his conclusions accord perfectly with those of the older physicians, who laid stress on the fact that the fever does not, as in smallpox, cease, nor even abate, upon the emergence of the eruption, but sometimes increases in intensity.

Exanthem.—The rash of measles first appears on the face; Ringer says that the earliest traces of it are seen on the forehead close to the scalp. It spreads over the face (not avoiding the parts about the mouth) and also over the whole trunk; on the limbs, especially the lower limbs, it generally comes out rather less freely, but it shows no decided predilection for the flexor surfaces, and it may be well marked upon the palms and the soles. In several of these minor points it differs from the eruption of scarlet fever The rash commonly takes three days for its complete development, but sometimes not more than a few hours; the later it is in beginning, the more quickly it diffuses itself over the body. Thomas says that before it has existed at any one spot for twenty-four hours it always begins to decline, so that when it comes out slowly it fades upon the face and neck, while it has still to make its appearance over the more distant parts; but according to Watson it may remain three days at least on the face before its subsidence commences. The old doctrine that a rapid retrocession of the rash was often followed by some dangerous complication is disputed by Thomas, in common with many other modern writers. On the other hand, he says that there is sometimes a brief recurrence of the exanthem when from any accidental cause there is an exacerbation of the fever.

The colour of this rash is a more or less deep rose or crimson, inclining to purple rather than to scarlet. It consists of spots of irregular form and of varied size. They are at first isolated, but afterwards coalesce into patches, the margins of which are sharply defined, and here and there present rounded notches, or (to use the current expression) are "crescentic" in outline. They are slightly raised; even the earliest papules can be distinctly felt with the finger. They have been supposed to be enlarged normal papillæ, or, again, to be the hyperæmic mouths of sebaceous follicles; but Gustav Simon, having excised a portion of the skin from a patient affected with measles, examined it histologically with negative results. When there is much sweating, a few vesicles of miliaria are sometimes to be seen. Before it subsides, the eruption acquires a yellowish tint, which is particularly well marked when the blood-vessels are temporarily emptied by the pressure of one's finger. This is no doubt the result of the diffusion of altered blood-pigment in small quantity into the substance of the cutis; for even in cases which are doing well, it is no uncommon thing for actual hæmorrhage to occur; so that, after the rash has faded, purple stains remain, which afterwards become brown and yellow, and do not finally disappear for two or three weeks.

Slight desquamation takes place, especially from the skin of the face. No large scales are detached, but only a fine mealy powder, which (as Trousseau remarks) is often best seen when one brushes the skin of the patient with one's coat-sleeve, or (according to Ringer) when the surface is stretched and viewed sideways. Desquamation begins on the sixth or seventh day of the fever, and continues for a week or ten days.

Convalescence is established about the end of the week, unless it is delayed by complications or sequelæ. The patient continues highly contagious during that period.

Varieties.—In many cases measles runs an irregular course, and, like those of other exanthemata, its aberrant forms are of two kinds: some *benign*, being shorter and more favourable than usual; others *malignant*, attended with very grave symptoms, and ending more or less rapidly in death.

In some benign cases of measles there is a rash, but no catarrh; in others it is the rash which is absent. Of *morbilli sine catarrho*, Thomas remarks that it is especially apt to occur in very young infants, and that it is almost unattended with fever. There is reason to believe that many cases of rubeola, or "German measles," were formerly supposed to be slight measles without catarrh, and perhaps this explains Sir Thomas Watson's remark that the incomplete form of the disease confers no immunity against recurrence. Dr Eustace Smith thinks it questionable whether *morbilli sine catarrho* is measles at all.

Of *morbilli sine morbillis*, Thomas observes that this form is in all likelihood diagnosed more often than it really occurs; but surely the only cases in which one would think of suspecting its presence would be if during an epidemic an unprotected person should suffer from catarrhal symptoms without any apparent cause. Some writers have asserted that, as in the case of latent scarlet fever, doubt may ultimately be removed by the occurrence of desquamation; but this is so slight, even when the affection of the skin is intense, that one would hardly expect to see it when there has been no eruption at all.

Of the malignant varieties of measles, there is one which is attended with hæmorrhages from the mucous surfaces, and with an intensely *purpuric* form of eruption. At the present day, however, this is very infrequent; it is observed chiefly in young and sickly children. Hence, when one finds the older writers laying great stress upon "black measles," one is almost inclined to suspect them of having mistaken cases of hæmorrhagic smallpox for this disease; and it is interesting to notice that Sydenham speaks of an unusually bad kind of measles as prevailing in London in 1670 and 1674, at a time when variola also was remarkably malignant and fatal. The hæmorrhages are said sometimes to begin before the ordinary morbillous rash comes out, sometimes afterwards, and then the exanthem quickly fades or turns of a livid purple colour. Petechiæ and vibices cover the skin, while blood oozes from the mucous membranes of the nose, kidneys, and intestines, as well as into the substance of the deeper tissues and internal organs. Death generally takes place within a very few days.

In other instances measles becomes fatal by the severity and prolongation of symptoms which are not in themselves unusual. The fever is from the first intense and persistent; the rash, although it may come out early, is of a livid colour, and often develops itself very imperfectly; instead of

the temperature falling about the eighth day, it remains high throughout a second week; the pulse is very rapid and feeble, the patient becomes delirious and drowsy, and passes into a "typhoid" condition with a dry brown tongue and sordes on the lips. Death is preceded by prostration and collapse.

One of the most important clinical uses of the thermometer in measles is to prove that cases of this kind deviate from the ordinary course of measles. According to Thomas, it is no less unfavourable for the temperature to be low when the eruption is coming out than for it to continue high at a time when it should be falling.

Complications.—It is a rule, to which there seems to be scarcely an exception, that in all but the most rapid hæmorrhagic cases of measles some complication or other is really the cause of death. Even when the symptoms are not sufficiently marked to lead to its recognition during life, a local lesion is sure to be discovered at the autopsy; and in cases that recover similar affections are very frequent, and often seriously modify the symptoms.

Broncho-pneumonia, with consolidation of scattered lobules throughout the lungs, is the most frequent complication, particularly in certain epidemics; indeed, it occurs so often that some writers have been disposed to include it in the regular course of the disease. But it is not really constant. The effects of this catarrhal inflammation of the lungs are the same as when a like affection arises from other causes. In some instances lobar pneumonia is found, and sometimes, perhaps, there is capillary bronchitis, but these are exceptional. More or less extensive pulmonary collapse often follows in young children.

A dangerous but happily rare complication is the formation of a layer of plastic exudation upon the fauces or within the larynx, a secondary membranous croup or *diphtheria*, according to the view which is taken of such morbid changes.

Again, in many cases, *diarrhœa* sets in so severely as to bring about a fatal issue, especially when the evacuations assume a dysenteric character. Little more than redness of the mucous membrane of the colon is found after death from this cause.

Epistaxis is not infrequent in measles, and occasionally serious. Among the less grave complications, so far as the life of the patient is concerned, must be mentioned certain affections of the eyes and ears. *Ophthalmia* is common, and often runs on for a long time after recovery. The author once saw a diphtheritic membrane form again and again on the conjunctiva. Sometimes iritis occurs, and sometimes destructive corneitis. In other cases the morbid action extends from the fauces along the Eustachian tube, causing *deafness* and pain in the ear. As a rule, it seems merely to lead to an accumulation of mucus in the tympanic cavity: but now and then suppuration takes place, and even necrosis of part of the temporal bone. Trousseau relates one instance of this, and another has come under the author's observation.

Sequelæ.—Almost any of the complications of measles may be so prolonged as to become a sequela; but there are some other affections which have a better right to that title, since they do not begin until after the patient has recovered from the primary disease. Among these is a form of gangrene, attacking the mouth (*cancrum oris*) or the female genitalia (*noma*).

According to Thomas it does not arise spontaneously, but is preceded by some slighter lesion of the same parts, such as a decayed tooth, or infantile leucorrhœa. It is generally, but not always, fatal.

In other cases measles is followed by *necrosis* of a portion of the upper or lower jaw, or by abscesses in the neck.

Again, children often remain for many months after recovery from this malady in a state of ill-health for which no obvious cause can be found, and during this time they are very apt to be seized with bronchitis, or sometimes by lobar pneumonia, especially in the cold seasons of the year.

The swollen bronchial lymph-glands may become caseous, and thus *tuberculosis* is not unfrequently set up. Indeed, this is one of the commonest and most fatal evil results of measles. An intercurrent attack of measles is said greatly to accelerate the downward course of a pre-existing phthisis.

On the other hand, certain cutaneous diseases, such as eczema, seem often to be favourably modified by the supervention of the exanthem, at least for a time; and, according to Rilliet and Barthez, the same thing happens in some cases of epilepsy, chorea, or incontinence of urine. In 1877 we had a case of paralysis probably due to peripheral neuritis which had followed an attack of measles.

Dr Goodhart finds that whooping-cough is often a sequel of measles, more often than its predisposing cause.

Protection.—Measles often fails in preventing a second attack. Even relapses are not unknown, and second or third invasions in a lifetime are not uncommon.

Diagnosis.—This depends on the late appearance of the eruption, the coryza, and the colour, distribution, and form of the rash. Measles has been mistaken for smallpox; but the symptoms are far less severe, the papules look and feel different, and the non-development of pustules decides the point. It is more often mistaken for scarlatina, but the eruption is later; it is purple, not scarlet, blotched, not punctate, and appears first and is most marked on the face. It is often confounded with Rubeola, or German measles, to be described in a following chapter.

Prognosis.—The mortality of measles varies widely in different epidemics. It has sometimes been so low as 2 to 3 per cent. of those who have been attacked, sometimes as high as 50 per cent. Malignant cases, killing within the first week by prostration, with or without a hæmorrhagic rash, are rare—much rarer than the corresponding malignant scarlatina; and petechiæ are often seen in ordinary benign cases. Trousseau relates that in 1845 and 1846 he lost from broncho-pneumonia twenty-two out of twenty-four children with measles who were under his care in the Necker Hospital. According to Thomas the few cases which occur during the first six months of life are generally mild; but the disease is more severe in infants during dentition than in older children. Convulsions, occurring after the rash has appeared, are of ill-omen.

Among adults measles is more severe than in children. It is most dangerous to women who are pregnant, or who have recently been confined, and to the very few old people who are susceptible of the disease.

Treatment.—The general plan of treatment is that suitable for febrile diseases in general, for we have no specific method of dealing with the

malady. The patient should be confined to the house, but only kept in bed if the temperature is high or the catarrh severe. He should be lightly clothed and allowed to drink as much water as he likes.

Poultices may be applied to the chest, but with little children a cotton-wool jacket is better, since it interferes less with breathing and does not get cold or slip off.

In ordinary cases of measles no drugs are required. The child should be kept in bed if the temperature is high and given plenty to drink—cold water, lemonade, raspberry vinegar, or any other cooling beverage. If the appetite continues, as it sometimes does, light solid meals may be allowed. When the cough is troublesome, black-currant jelly or sweetened barley water slowly swallowed relieves the irritation of the fauces and thereby the cough. Or a few drops of ipecacuanha wine with ten or fifteen of paregoric, sweetened with syrup of tolu, and given every two hours, promote secretion, and thus may relieve cough and procure sleep.

If the temperature is not above 104°, aconite, thallin and other antipyretics probably do more harm than good, and cold baths are undesirable; but sponging is of comfort and use. Bronchial complications may call for ammonia, and pneumonia or collapse, or great depression with persistent high temperature and rapid pulse must be met by the exhibition of brandy. Diarrhœa is not a good symptom, and should be checked by chalk or bismuth, by withdrawing beef-tea and substituting arrowroot, with milk and lime-water. Purgatives at any stage of the malady are undesirable. In severe dyspnœa from bronchitis, laryngitis, or pneumonia, Dr West records recovery after the application of leeches or venesection. Dr Eustace Smith recommends dry cupping.

During convalescence, the chief dangers are fresh bronchitis, whooping-cough, or the supervention of caseous disease of the bronchial lymph, and consequent phthisis. To guard against these the child should be well fed, and, if needful, the appetite helped by quinine. Anæmia should be combated by steel, and want of nutrition by cod-liver oil. The body should be warmly clothed in flannel and the child allowed to be much in the open air.

It must be remembered that measles is infectious from the very beginning of the disease, so that isolation should be enforced as soon as its presence is recognised.

SCARLATINA*

"This distemper is sometimes so slight as to require no remedies, and sometimes so violent as to admit of no relief."—HEBERDEN.

History and Nomenclature—Distribution—Contagion and transference—Surgical and puerperal scarlatina—Incubation—Onset and Course—The throat—The rash—Abortive and malignant varieties; scarlatina anginosa—Complications and sequelæ—Anatomy—Prognosis — Protection — Prophylaxis—Treatment.

SCARLET FEVER was recognised and discriminated as a distinct disease by Sydenham in 1675, and the separation from measles was completed by Withering a century later (1778). It had, indeed, been described as far back as 1556 by Ingrassias under the name of Rossalia, at Naples, and again by Döring, at Breslau, in 1627; but even Morton, who was a contemporary of Sydenham, maintained that it was only a variety of measles. The distinctive name *febris scarlatina* (Ital. *scarlatto* = *scarlet*) was given by Sydenham. It is remarkable that he did not mention sore-throat as one of its symptoms. Probably the bad cases of Sc. anginosa were then called *Cynanche maligna*, which was distinguished as late as Cullen and Heberden.

From the persistence and virulence of its contagion and from the severity of its effects, this disease is justly dreaded. Since the introduction of vaccination, it has taken the place of smallpox as the most common and fatal of all the specific fevers.

Its geographical distribution is now very wide, but like smallpox and measles, relapsing fever and typhus, it has been introduced from Europe into other parts of the globe within historical times. Thus it appears to have been unknown in the colonies of North America until the year 1737, and in South America for nearly a century later (1829). It was brought to Iceland in 1827, to Greenland in 1847, and about the same time the first cases were recorded in the Australian colonies.

Ætiology.—The channels and mode of entrance of the contagium are not always the same. The dry epidermic dust is probably most often taken in with the air in breathing, or with food and drink in swallowing. It is often conveyed by clothing or other fomites.

Attempts to reproduce scarlatina in the lower animals by transference of blood or epidermis have repeatedly failed; but investigation into a remarkable epidemic at Hendon in 1885, by Dr Power and Dr Klein, appears to render it probable that Scarlatina may not only be conveyed from one person to another by means of milk, as before ascertained, but that the disease may originate in cattle, and be conveyed from them by their milk to children.

The *contagium vivum* is chiefly present in the epidermis which is shed.

* *Syn.*—Scarlet Fever—Morbilli confluentes (Morton, 1700)—Febris rubra (Heberden).—*Fr.* Scarlatine, *Germ.* Scharlach, *Ital.* Febbre Scarlattina.

It is particulate, but although several forms of micrococcus and bacillus are present in the secretions of the fauces during the disease, and have been described by McKendrick in 1872, and by Pincus in 1883, none have been certainly identified as pathogenic or even as characteristic. Dr Klein has since, he believes, succeeded in reproducing the disease in cattle ('Proc. R. S.,' March 3rd, 1887), by inoculating them with micrococci obtained by cultivation from the blood of cases of human scarlatina, and also by feeding calves with the same microphytes suspended in milk.*

The contagion of scarlatina, though active and very persistent, is not easily diffusible. Thus, it rarely crosses a street, and epidemics do not spread so quickly as those of typhus, measles, variola, or diphtheria. But they linger long and die slowly out.

Although scarlet fever never arises but by contagion, yet, as in other cases, there are conditions which predispose to receiving and developing it.

First of these is the *age* of the recipient. It is rare in infants, most common in early childhood (Murchison found 64 per cent. of cases to occur between the ages of one and five), and rare after puberty; but it may occur even in advanced age. When measles and scarlatina are both rife in a town, it has often been remarked that very few unprotected persons escape the former and many the latter.

Secondly, puerperal women are peculiarly liable to take the contagion; and, with somewhat masked features, it forms a considerable proportion of the cases known as puerperal fever. Dr Braxton Hicks found that in eighty-nine cases of this terrible disorder no fewer than thirty-seven either showed a scarlatinal rash or had been subjected to infection from patients with scarlatina.

Thirdly, persons who are suffering from wounds are extremely prone to infection. The sore-throat and fever are frequently present without the rash, or the rash is slight and quickly over. But that the affection is genuine scarlatina is proved by its "breeding true" and by its protecting against future attacks. Moreover, although most of these cases are mild, like inoculated smallpox, occasionally a severe one occurs along with the rest and exhibits the sequelæ as well as the symptoms of the disease. Sir James Paget and Mr Howse, Dr Gee, Dr Eustace Smith, Mr E. C. Stirling, and Dr Goodhart have placed the true nature of this "surgical scarlatina" beyond doubt. It is remarkable that according to the observation of the last-named author, antiseptic precautions do not prevent the infection, so that the otherwise probable supposition that the contagion gains a direct entrance through the open wound appears to be untenable.

The *season* in which Scarlatina is usually more prevalent is in the autumn months from the middle of September to mid November. This was observed by Sydenham, who wrote: "Scarlatina febris licet nullo non tempore possit incidere, ut plurimum tamen exeunte æstivo se prodit" ('Obs. Med.,' sectio vi, cap. 1).

Incubation.—This period is short compared with that of enterica, typhus, measles, or smallpox. It most commonly lasts between two and six or seven days. Occasionally the interval between infection and the first symptoms may be still shorter, twenty-four hours, or perhaps even less. Among the cases with the shortest incubation are those of puerperal and surgical scarlatina just mentioned. Although rare, instances occur in which

* See also a paper by Drs Jamieson and Eddington, with figures of the bacillus which they selected as probably pathogenetic ('Brit. Med. Journ.,' June 11th, 1887).

more than a week has elapsed between contact with a case of scarlatina and appearance of its first symptoms, and still more rarely the incubation may be as long as that of smallpox or of measles.*

Course.—The onset of the disease is generally sudden. In children the first symptom is often vomiting or a convulsive seizure. In adults it is usually soreness of the throat, and there may be chilliness or even a rigor. The patient complains of headache, malaise, and prostration.

The face quickly becomes flushed, the pulse remarkably rapid, and the skin hot. For a child's pulse to be at 140 or 160 within a few hours is not uncommon, nor of unfavourable augury; and it may remain high for several days.

The *temperature* may rise to 104° or 105° in the course of the first day or it may attain the same point or a still higher one more slowly afterwards, while the rash is coming out. It then as a rule rests stationary, or nearly so, until the rash begins to fade. The extreme dryness of the surface is apt to give one an impression that it is hotter than is really the case; from the time of Addison we have spoken of the pungent heat of the skin in scarlet fever as comparable only with that of acute pneumonia.

Dr Gee describes the fever as frequently ending in a complete crisis; this occurred in two of his cases on the fourth day, in four on the fifth, and in three on the seventh. But its fall is more often gradual, taking from three to eight days for its completion. After the fever is over the temperature is often subnormal for a day or two.

The *urine* is scanty and high coloured as in other fevers, an abundant precipitate of lithates forms as it cools, and it often contains a little albumen even at this stage. Urea is in great amount, and the proportion of potash salts is increased.

The *tongue* is at first coated with a thick creamy layer, as in other febrile diseases. But before long enlarged fungiform papillæ are seen projecting as shining scarlet points, and after two or three days the white fur clears away from before backwards, leaving a smooth bright red surface; this, with the little prominences that are thickly scattered over it, has an appearance that has been compared with that of a strawberry. Sometimes, however, no such enlargement of the fungiform papillæ occurs. German writers speak of a miliary vesicular eruption as occasionally present, especially on the dorsal surface. The tongue does not regain its normal aspect until convalescence has set it.

On looking at the *fauces* one finds the arches of the palate, the uvula, and the tonsils more or less reddened or purple. Sometimes, but not always, they are swollen; and the redness may extend to the roof of the mouth and to the pharynx. Swelling of the mucous glands often gives a granular appearance to the affected parts; and their secretion may accumulate upon the surface so as to simulate the presence of ulcers. The tonsils may even project inward until, with the club-shaped uvula, they block up the passage; and after a few days one or both of them may suppurate. There is often swelling of the neighbouring cervical lymph-glands.

Exanthem.—The rash generally makes its appearance in from twelve to

* In one case, under my own observation, a child left his father's house, where three of the family had died from scarlatina, on November the 19th and continued well until December the 2nd, when he developed the disease, just a fortnight after the last exposure to contagion. It is, however, possible either that the infection was from a different and more recent source, or that it was derived from fomites which, notwithstanding every care, may have been carried away with him from the house.—P. H. P.-S.

thirty hours after the commencement of the disease. Sometimes it is later; but, as Dr Gee remarks, the proof of this is difficult, not only because the first signs of it are easily overlooked, but because it may recede for a time, and then come out again. In some of the more severe cases it is altogether ill developed, and writers say that it may then be delayed until the third or the fourth day. In the great majority of cases the rash begins to appear towards the end of the first day, and is fully out on the second.

As a rule, the eruption is first to be discovered upon the sides of the neck and the upper part of the chest; and it generally takes twelve or twenty-four hours, or even two or three days, to reach its full development But sometimes it comes out almost at once over a very large surface. The face often remains free; and, when present, the rash is in most cases limited to the forehead and temples, the cheeks showing only the ordinary flush of fever, while the parts round the mouth, nearly to the chin, remain pale. The upper arms are often covered with the eruption, and it is exceedingly well marked on the abdomen and on the inner side of the thighs.

The colour is usually a bright scarlet, so that Watson aptly compared it with that of a boiled lobster; but sometimes it is of a lighter pink, and sometimes purplish. It may appear to be uniformly diffused, but on careful examination one can generally see that it is made up of very minute red points, which are at first isolated from one another, and which, even when they have coalesced, often leave a little islet of healthy skin here and there. This minutely punctated appearance is even more distinct from the "blotchy" aspect of the rash of measles than the bright crimson of the one from the rose-tint of the other. It momentarily disappears on pressure except where there has been some degree of hæmorrhage or perhaps capillary stasis, in which case isolated red spots remain, with a more or less general yellow discolouration. As Watson long ago pointed out, on the forearms and the legs, as well as on the backs of the hands and of the feet, the rash of scarlet fever consists of larger and more prominent papules than elsewhere; the palms and the soles, however, show only a faint diffused blush through their thick epidermis. The skin of the affected parts is slightly turgid or even swollen; the eyelids and the cheeks look a little puffy. Trousseau remarks that tumefaction of the fingers often prevents the patient from closing his hand.

Löschner discovered exudation-cells in the rete Malpighii, and probably they were seen by Dr Fenwick also, who further observed that the basement membrane of the sweat-glands was thickened, and their channels were obstructed by an overgrowth of epithelium, or by extravasated blood. That the scarlet fever eruption bears no definite relation to these glands, nor to the hair-follicles, seems to follow from a case (cited by Thomas on the authority of Landenberger) in which it did not fail to develop itself over an immense cicatrix, the result of a burn which was said to have destroyed the whole thickness of the skin.

Certain modifications of the eruption of scarlet fever are sometimes observed. Instead of being punctiform, it may in rare cases consist of large, irregular, slightly raised maculæ, more or less like those of measles, or it may be markedly papular. Or, again, it may be associated with immense numbers of miliary vesicles, especially upon the neck and chest, when there has been much perspiration.

At a variable period after the subsidence of the rash—which has usually faded by the end of the first week, often on the fifth day and sometimes earlier

—the superficial layers of the cuticle begin to peel off, or, in technical language, to *desquamate*. This is sometimes observed within a few days, sometimes not until two or three weeks have elapsed. Its amount is not necessarily proportionate to the intensity of the cutaneous affection; it may be well marked where the rash was so slight as to have been overlooked, and so may be of service in clinching a doubtful diagnosis. In some cases it assumes a furfuraceous form; a mealy powder, or a fine scurf, becoming detached from the surface, especially from the face. But more generally it is "membranaceous;" distinct flakes come away, and may be some inches long. The first step towards the throwing off the epidermis at a particular spot is often the formation of a little opaque raised vesicle, very like those which are characteristic of eczema, but dry; this breaks at the summit, leaving a free edge in the shape of a ring, which gradually becomes larger and larger. The cuticle of the hands is now and then shed *en masse*, like a glove; and the same may be the case with the feet; in some cases not even the nails are left behind. So complete a desquamation as this necessarily takes several weeks for its completion.

Much more often the fact that the exanthem interferes for the time with the nutrition of the nails, is shown, not by their exfoliation, but by the formation of a transverse groove: to this Dr Wilks has especially drawn attention. It is seen upon several of the nails at equal distances from their roots, and of course it ultimately becomes lost at their distal extremities. Such grooves on the nails are not, indeed, peculiar to scarlet fever, being sometimes seen after other acute diseases; but even with this qualification, their presence sometimes throws valuable light upon the origin of sequelæ, the real nature of which might otherwise have remained undetermined. The hair comes off with the cuticle; but perhaps not more than after any other fever of equal severity.

Desquamation follows the same course as the rash, beginning on the chest, shoulders, and neck, then spreading over the arms and back, and then over the lower extremities. It is often delayed in the hands and feet until long after the rest of the skin is clear.

Aberrant forms.—A striking feature of scarlet fever, and one upon which all writers lay stress, is the great variability of its symptoms and of its course; so that, indeed, there is much difficulty in describing all the different forms it may assume. In this, as in some other characters, it resembles enteric fever.

In some cases the disease is *rudimentary* or *abortive*. Thus, during epidemics, it often happens that adults become more or less feverish, complain of a slight sore-throat with redness of the mucous membrane, and have a little pain and swelling of the cervical glands, but are at no time really ill. This is especially apt to be the case with those who have already had an attack in childhood; medical men say that it has again and again occurred to them, when attending patients suffering under scarlet fever. But the author saw an instance in which a father so affected gave to his children a disease of such severity that one of them died. Again, the chief symptom may be feverishness, so that the complaint passes for a mere febricula, there being little or no affection of the throat, and no redness of the skin beyond what might be attributed to the pressure of clothes or to some other accidental circumstance. Lastly, the sole indication may be an eruption, and this perhaps limited to a small part of the surface. The real nature of this affection is often first shown by the occurrence of

desquamation, or even by the unforeseen supervention of dropsy or of some other of the sequelæ of scarlet fever.

In a very different class of cases, the symptoms are incomplete because the end comes too quickly for their full development. In several recorded instances the patients have died in from eight to fifteen hours; the chief phenomena have been delirium or coma, convulsions (or occasionally tonic spasms with trismus), incessant vomiting and diarrhœa, with extreme rapidity of pulse and of breathing. Sometimes there has also been hyperpyrexia, in which case one would be inclined to regard this as determining the form of the disease. A temperature of 115° F. was observed by the late Dr Woodman in some patients. The only thing that could render a diagnosis possible would be the occurrence of other cases of scarlet fever in the same neighbourhood. The writer saw a little boy with Dr Andrews in 1883, who was taken ill the same morning with severe headache, vomiting, and prostration. When seen he was already comatose, but there was no exanthem. The temperature was 105·6°, the skin was pungently hot, and the pulse too rapid to be counted. Such a condition could be due only to smallpox or scarlatina, and the presence of good vaccination marks, together with the characters of the skin and pulse, justified the latter diagnosis. He died the same afternoon; and the nature of the case was confirmed by the child's nurse afterwards sickening of scarlet fever.

The cases just referred to constitute the most extreme examples of what in England is commonly called *malignant* scarlet fever. But there are other varieties which are almost as certainly though less rapidly fatal. Sometimes, with early severe constitutional symptoms of a "typhoid" character, the rash comes out late and imperfectly, and its hue is not bright scarlet, but rather a livid violet. In other cases the disease assumes a *hæmorrhagic* form; at least, almost all writers say so except Dr Gee, who is evidently inclined to think that the early hæmorrhagic roseola of smallpox may have been mistaken for it.

Sometimes, again, the eruption develops itself in the regular way; but the febrile disturbance, which from the first is high, runs on for two or three weeks instead of subsiding after a few days. The patient then falls into a typhoid state, with muttering delirium, a dry brown tongue, and sordes upon the lips. Many of these cases end fatally. In a large proportion of them the affection of the throat is unduly severe. Sometimes the fauces become gangrenous and slough away, leaving a horribly offensive cavity. The inflammation often spreads to the lining membrane of the nose, and an acrid fluid flows from the nostrils, which excoriates the upper lip. The nasal bones may even become necrotic. Still more frequent is extension to the ear along the Eustachian tube; the tympanum then fills with pus, which is discharged by perforation of the membrane. Here, again, there is often great destruction of the tissues: Sir Thomas Watson mentions a case in which, every time that the child swallowed, some of the liquid ran out at one of its ears; and it is no uncommon thing for fatal hæmorrhage to ensue from perforation of the carotid artery.

Faucial diphtheria is a very dangerous complication, and sometimes occurs in almost every case in a local epidemic. It is doubtful whether we should look on it as a local variety of scarlatina or as a combination of this malady with diphtheria.

In other cases, the chief local mischief is outside the throat, in the cervical lymph-glands and the adjacent structures. A large swelling may form

on each side of the neck near the angle of the jaw; or the whole space from the chin to the sternum may be occupied by a brawny shining mass, which has been termed a "collar." It does not appear that the salivary glands, whether parotid or submaxillary, take any part in this affection. The induration of the connective tissue may spread backwards between the pharynx and the spine, or downwards into the mediastinum. If suppuration occurs, the pus may be discharged by a series of fistulous openings, burrowing and undermining the skin in all directions; or a post-pharyngeal abscess may be formed, which, pressing on the larynx, may cause suffocation. Extensive sloughing often takes place, so that the muscles are laid bare, as in a clean dissection; and dangerous or fatal hæmorrhage may ensue, from perforation of one of the arteries or veins of the neck.

Complications and Sequelæ.—Some of the affections just described might be reckoned under complications of scarlet fever. We may, however, certainly give that name to one morbid condition which is comparatively rare, and is unrepresented in the normal course of the disease. This complication, which is by no means confined to cases of great severity, is *synovitis*, a painful swelling of some or all of the joints. It generally sets in while the skin is peeling, and affects sometimes the smaller, sometimes the larger articulations; it generally subsides quickly, and it is even more fugitive than the synovitis of ordinary rheumatism. In some cases, however, it settles into one particular joint, leading to chronic effusion, or even to suppuration. Probably most cases of synovitis following scarlatina are true rheumatism.

Dr Ashby, of Manchester, finds synovitis *in the course of the fever* to be very rare and unaccompanied by evidence of cardiac inflammation. Subsequent rheumatism is less rare in young adults than in children. Endocarditis (rheumatic or nephritic) is less common as a sequela than dilatation of the heart.*

A more frequent complication of scarlet fever is acute *nephritis*, accompanied with albuminuria. Whether any affection of the kidney is present in ordinary cases of scarlet fever, which end in recovery, appears to be still doubtful. Thomas remarks that the question could be settled only by the microscopical examination of the organs from a patient killed by an accident during the course of the disease. It is certain that nephritis has been found after death in some exceptional cases of scarlatinal dropsy in which the urine, although scanty, contained neither albumen nor casts during life. This fact obviously suggests the possibility that renal changes may be present in cases which do well, without any evidence being discoverable. It is also certain that the more assiduously one tests the urine throughout the whole course of the disease, the more numerous are the cases in which a trace of albumen is detected at one time or another. Thus some German writers look upon a renal catarrh as bearing to scarlet fever the same relation which bronchial catarrh bears to measles. But albumen and occasionally even tube-casts are found in the urine in other febrile diseases, so that their presence is not necessarily to be taken as part of the action of a specific poison upon the kidneys. Scarlatinal *dropsy* will best be discussed with the anasarca that results from other acute forms of tubal nephritis. Anasarca without albuminuria is occasionally met with after scarlet fever.

Serous inflammation.—Pleurisy and pericarditis are of rather frequent occurrence, usually in connection with the affection of the joints, and this confirms the view of its rheumatic character. This may also be attended

* 'Lancet,' May 22, 1886. Compare the report from Glasgow ('Clinical Trans.,' 1885–6).

with endocarditis, and so may doubtless be the starting-point of chronic changes in the valves of the heart; but whether this ever arises when the joints have remained free appears to be doubtful. In making *post-mortem* examinations of children who have recently had scarlet fever without synovitis, we have always found the valves healthy. Pleurisy and pericarditis, or pneumonia, may also accompany scarlatinal nephritis.

Chronic enlargement of the *tonsils* is very common in children who have passed through this exanthem.

Far more important sequelæ are various affections of the *ear*. Indeed, scarlatina is almost always the explanation of deafness acquired in early life. The most frequent local lesion is acute suppurative tympanitis produced by extension of the faucial inflammation along the Eustachian tube. It often leads not only to perforation of the membrane, but to necrosis of the petrosal bone, and subsequent fatal pyæmia. Necrosis of other bones is not very uncommon, and glandular abscesses sometimes follow during convalescence.

An important complication, sometimes occurring in the first week, sometimes not until convalescence, is *diarrhœa*. It occasionally leads to fatal exhaustion.

Anatomy.—Little that is distinctive is found in examining the body after death from scarlatina, beyond the appearances due to fever as such, and those produced by any complications which may have been present during life. No trace of the rash remains, although the presence of desquamating cuticle may give a hint of the nature of the disease in cases not seen during life. Even the inflammation of the fauces leaves very slight effects. Occasionally the heart is found in a state of acute dilatation, as after some cases of diphtheria. There are not infrequently signs of intestinal catarrh with slight swelling of Peyer's patches. The kidneys are large, and show either glomerular nephritis or ordinary tubal inflammation.

Prognosis.—The prognosis of scarlet fever can never be altogether devoid of anxiety, for in the mildest case some dangerous complication may arise. Sporadic cases are sometimes quite as severe as those which form part of an epidemic; and epidemics differ widely in their gravity. One prevailed for many months in a country town in Kent without there being a death, and without dropsy ever supervening, and Dr George Turner observed an epidemic of 120 cases at Portsmouth without a single death. Graves recorded the fact that whenever scarlet fever appeared in Dublin between 1805 and 1833 it was always mild, so that on one occasion eighty children were attacked in the same public institution, and all recovered; but during 1834 and 1835 the city was the seat of a very malignant and fatal epidemic. Thomas says that in Saxony a mortality of from 13 to 18 per cent. is very common, but that it not infrequently rises to 25, and sometimes even to 30 or 40 per cent. Scarlatina in adults is usually less severe than in children; in puerperal women, however, it is notoriously dangerous, though far from being always fatal.

Most of the inferences to be drawn from particular symptoms have already been indicated. But it may be added that, according to Trousseau, the occurrence of convulsions during the first or second day is always a sign of danger, whereas in other exanthemata it is not of evil omen. Another point which is made by this writer is that in scarlet fever, as in smallpox, the more intense the rash the more severe is the disease. Here, however, he differs from most other observers; and the statement perhaps only

means that those cases in which a bright red eruption covers the whole of the body, and lasts for an unusually long time, are generally grave ones, whereas when the eruption is slight and quickly over the fever also is moderate and of brief duration.

Protection.—This is less complete than in the case of typhus, enterica, smallpox, or perhaps measles. Second and even third attacks are not very uncommon. But they occur after a considerable interval; and relapses, though not unrecorded, are certainly very rare.

We have no means of *prophylaxis* but isolation. Belladonna was supposed to be indicated by the fact that poisoning by belladonna produces dryness of the throat and a roseolous eruption, just as in former times red curtains were hung round a patient's bed because of the colour of his skin. It has, however, been fully tried, and conclusively proved to be useless. Arsenic has been credited with a similar power, probably on insufficient grounds.

Treatment.—When the contagion has been once taken in, we must be content to treat scarlatina on the same general principles as those indicated in the chapters on Typhus and Enteric Fever.

In mild cases little is needed beyond careful isolation and free diluents. Tepid baths and sponging the surface is grateful in almost every case.

When the temperature is very high, 104° or upwards, we must check it by cold sponging, wet packs, rubbing with ice, or cold baths, as described above (p. 172).

The angina causes much pain and difficulty in swallowing. Sucking ice gives great relief; and, if the patient will allow it without too exhausting a struggle, it is useful to clear the throat with a large camel-hair brush or with cotton-wool firmly tied on to a penholder; or a spray medicated with thymol, carbolic acid, or some other disinfectant, may be employed. Older patients may use Condy's fluid or chlorate of potash as a gargle, or borax and honey as a linctus, with advantage. In severe cases nutrient enemata or suppositories may be tried; and if they fail, as they unfortunately often do, the patient must be fed by the nose; not with a catheter—a child's nasal passages are too small, and the process would be too long—but by inserting a glass funnel, of the kind used for filtration in laboratories, into the opening of one nostril, closing the other, and pouring milk and egg, beef-tea, or other fluid nourishment into the pharynx. An aural speculum answers the purpose well.

Brandy must be given if the pulse requires it. Quinine in doses of five grains three times a day for a child of five years old is recommended by Dr Eustace Smith. Chlorate of potash is also of undoubted benefit in many cases of scarlatina anginosa.

As soon as the eruption is fully out, the whole surface should be anointed with carbolic oil (1 in 30); and when the fever has subsided and desquamation has appeared, the hair should be cut short, and the whole body well washed with hot soap and water, followed by inunction. A warm bath with soap may then be given daily. The oil is not only pleasant to the patient, but prevents the desquamating scales from flying about.

Great care should be taken during the stage of peeling to keep the patient from draughts. The body should be clothed in flannel, and any chill carefully guarded against. The urine should be daily tested, and while it contains albumen the patient should not be allowed to leave his bed or to take meat.

If, in spite of precautions, nephritis and dropsy follow, the case is one of

acute Bright's disease, and must be treated by purges and other means, which will be detailed in the second volume.

Rheumatism as a sequela is amenable to salicyl compounds—another proof of its true nature.

During convalescence, tincture of steel is the most useful drug, and port wine the best form of stimulant, when it is required. Even in mild cases the child should keep his bed for three weeks and his room for a month at least from the beginning of his illness (Eustace Smith).

The rules for disinfection given on pp. 24, 25 must be thoroughly carried out. The patient must not associate with other children until the desquamation has ceased, except perhaps that on the soles of the feet, which sometimes lasts for weeks after the rest of the surface is clear.

The infection of scarlatina begins later and lasts longer than that of measles or of smallpox, probably for six weeks, or even more.

RUBEOLA*

" Facies non omnibus una,
Nec diversa tamen, qualem decet esse sororum."
OVID.

Recognition and nomenclature—Its characteristics—Discrepancies and probable explanation—Incubation—Onset and course—Diagnosis—Protection—Prognosis and treatment.

SCARLET FEVER had not long been universally recognised as distinct from measles, when German physicians in the latter half of the last century began to describe a third member of the same group of diseases, for which they adopted the term " Rubeola." Ever since, the relation of this Rubeola or Rötheln to Morbilli or Masern† has been a subject of controversy.

In this country, Dr Paterson, of Leith, described the supposed third exanthem in the 'Edinburgh Medical Journal' for 1840, and among English writers it has since been recognised by Murchison, Squire, Bristowe, Robert Liveing, Eustace Smith, and Goodhart.

The term " epidemic roseola," adopted by Squire and by Bristowe from Trousseau, would convey the wrong impression that the disease bears some relation to the other eruptions which have been known as species of roseola since the time of Willan. Moreover, Trousseau believed that his " roséole epidémique " did not correspond with Rötheln or Rubeola notha.

On the whole it seems best to use the word Rubeola, first invented by Sauvage as a synonym of morbilli, and afterwards appropriated to " German measles " by Copland. Measles in English, and *morbilli* in Latin, are satisfactory names, distinctive and unambiguous. It is a pity to lose a word which has already been applied to a disease in want of a name, and which, if not so used, must be abandoned altogether. Moreover, Rubeola is the accepted equivalent of Rötheln with German authors.

Rubeola, then, is a specific and infectious febrile disease, occurring in epidemics, arising from contagion and breeding true, accompanied by an exanthem, and protecting against itself.

Its most essential features are that, with catarrhal symptoms like those of measles, and a variable but distinct rash, it resembles scarlet fever in having a very short prodromal stage and in being attended with marked sore-throat.

A favourite idea with some of the older writers (Schönlein among others) was that it was a " hybrid " between these two diseases; Niemeyer wrote of the symptoms alternating in different cases, so that sometimes the rash of measles would be associated with the local lesion of scarlet fever, and sometimes the reverse would be the case. But this was purely fanciful.

* *Synonyms.*—Rubeola notha, Rubella, bastard measles (Babington); German measles.—*Fr.* Roséole epidémique, *Germ.* Rötheln.

† According to Seitz *Rötheln* is a local or dialectic name for ordinary measles (*Masern*) in many parts of Germany.

There is no doubt that two specific exanthems may exist together in the same patient, but they do not combine so as to produce a modified affection; still less can such an affection be epidemic, or protect against itself, while affording no immunity against either of the constituent diseases.

In the first edition of this work, Dr Fagge contrasted the account given by Paterson, and accepted by Aitken and other systematic writers, with that of German authors, and especially with Professor Thomas's article in Ziemssen's 'Cyclopædia,' based on two epidemics at Leipzig in the years 1868 and 1872. In the former account we read of marked disturbance at the invasion, high fever, severe catarrh, with œdema of the glottis, bronchitis, severe angina with dysphagia, and a raised blotchy eruption appearing on the third or fourth day. Death was not infrequent from suffocation or from convulsions.

The discrepancy of this account from those given by Thomas and other German writers must be admitted, but possibly Paterson's epidemic was not rubeola at all, but measles. When the writer was a student at Guy's Hospital the crew of a Peruvian vessel in the Thames were attacked by measles, and the patients were taken into our wards. The disease was exceedingly severe, and several died from it, in almost every case from bronchitis or pneumonia. The same unusual malignancy marked the introduction of measles into the Fiji Islands.

However this may be, there can be little doubt that the disease described by Thomas, Eichhorst, and other German writers, by Bristowe, Liveing, Cheadle, Eustace Smith, and Goodhart,* is one and the same, different both from measles and from scarlet fever.

There was an epidemic among the nurses at Guy's Hospital a few years ago which satisfied all who saw the patients of the reality of the disease. The cases differed considerably in severity and in the character of the rash. Sore-throat was always present, and catarrh was much less frequent, so that it was very distinct from measles; while the absence of the characteristic signs of scarlatina and of any severe cases prevented confusion in that direction. Some of the mildest cases, when the patients were about, and therefore the rash not obvious, might have been set down as "epidemic sore-throat."

Rubeola occurs in the British Isles and on the Continent, in Egypt, in India,† and in America.

Origin and incubation.—All writers agree that rubeola arises strictly by contagion from other cases. The most important predisposing cause is age; it is more frequent about puberty, is rare in young children, and not common in adults. Boys in a family are said to escape oftener than girls.

The incubation stage is generally somewhat shorter than that of measles. In an epidemic at Guy's Hospital in 1888 several of our students were attacked, and the shortest incubation period observed was eight days, while one seemed to be as long as seventeen days. Of 86 cases observed with respect to incubation, it lasted six to ten days in 32, eleven to fourteen days in 45, and two or three days longer in 9 only. Bristowe puts

* The reader may also refer to a succinct but full account of an epidemic of fifty cases by Dr Douglas, of Newbury ('Brit. Med. Journ.,' May 26, 1877), and to a short paper by Dr Ryle (*ibid.*, July 24, 1886).

† Surgeon-Major McLeod read a paper before the Epidemiological Society (Feb. 11, 1885) on an epidemic rose-rash which visited Calcutta in 1881, and which he rightly decided to be rubeola.

it at about a week, or rather less; Squire about ten days; Liveing ten to fourteen days; Douglas fourteen or fifteen days, never more, and rarely less; while Thomas gives a fortnight or even three weeks. Dr Clement Dukes, whose opportunities as medical officer of Rugby School were exceptional and exceptionally used, states that out of twenty-four carefully observed cases the incubation lasted twelve days in two, and from fourteen to twenty-two in the rest.

Dr Haig-Brown recorded an epidemic of rubeola at the Charterhouse School in the 'Brit. Med. Journ.' for April 16th, 1887. He found the infection is apparently less active than that of measles and less persistent than that of scarlet fever, for more inmates of a house or school escape during an epidemic of rubeola than during one of measles, and cases seldom occur after an interval of cessation. Nothing is exactly known of the nature or the mode of conveyance of the contagion.

Onset and course.—As a rule the first symptoms are not severe. There is usually little or no catarrh before the rash, and the fever is not high.

The *exanthem* appears early; often it is the first symptom noticed, and it is scarcely ever delayed beyond twenty-four hours after the temperature rises. Among 159 cases it was out on the first day in 119, and on the second in 39. It is more like the rash of measles than that of scarlatina, but it is of a brighter rose tint; it is patchy, but less mottled and more diffuse than measles, while it is less vivid red, less diffused, and less punctate than scarlet fever. Its distribution is earliest on the forehead and cheeks, and afterwards the trunk, particularly the back. It is not so markedly developed on the face as measles. The upper arms are affected, the nates and the thighs; but seldom the hands and feet. There is often troublesome itching. It spreads more rapidly and less regularly than the other two exanthems.

The eruption lasts three days or more, usually longer than measles, but not so long as scarlatina. Desquamation is present, but needs careful looking for, and never resembles that of scarlet fever.

With the rash there is, in probably every case, angina; the fauces are injected and swollen, but there is never sloughing, and the lymph-glands at the angles of the jaw are usually not enlarged. On the other hand, the glands which run along the hinder border of the sterno-mastoid muscle can as a rule be felt. There is lacrymation with some photophobia, and usually slight nasal catarrh, accompanying but not preceding the exanthem. In exceptional cases this is followed by bronchitis. But catarrhal symptoms may be absent, and they are rarely so marked as in even mild cases of measles.

Pyrexia on the second day is sometimes rather high, with quick pulse, restlessness, and occasionally delirium; 100°—103° are the usual temperatures, but 105° has been more than once recorded. It subsides with the rash on the fourth day, and the pulse falls with it.

Traces of albumen are often to be found in the urine, and Dr Liveing has in exceptional cases seen it persist and anasarca follow. The tongue is moderately furred, and does not resemble that of scarlatina. Dr Douglas informs the writer that, in an epidemic in 1883–84, he twice saw "rheumatoid" synovitis affecting the wrists and lasting three or four days.

The whole attack lasts four to six days, about as long as an ordinary one of measles.

Sequelæ appear not to exist. Dr Goodhart affirms that if after an attack

of German measles a child remains thin and feeble, or has a discharge from the ears, the disease was either scarlatina or measles.

Diagnosis.—The first cases of an epidemic may often be doubtful; but after seeing a few, the eye recognises the peculiar aspect of the rash. Between slight cases of scarlatina and rubeola the distinction is often difficult: the desquamation in the former case is probably the most helpful point to look to. The early appearance of the exanthem (usually along with the fever) is the best distinction from measles.

It is often difficult to distinguish rubeola from "ordinary rose-rash," whether set up by gastric disturbance or definite poisons, or caused by local irritation. Dr Dukes says that the roseola produced in some persons by handling the hairy larvæ of certain moths (the "woolly bears" which schoolboys collect) is sometimes exactly like rubeola. There is no doubt of the existence of a generally diffused bright red eruption, which, though not contagious, appears in groups of cases in hot weather. The name "roseola," or rose-rash, is suitable for this affection, which is quite distinct from true erythema multiforme (to be described under Diseases of the Skin) as well as from rubeola, from morbilli and from scarlatina. It is clear from the absence of catarrh and sore-throat, from the severe itching, and from the proneness to relapse, beside many other characters, that this affection, graphically described as Roséole by Trousseau ('Clinique Medicale,' tome i, p. 161) and as Erythème scarlatiniforme by Hardy ('Leçons sur les Mal. de la Peau,' 2me partie, p. 35), is not—as the late Dr Tilbury Fox ('Skin Diseases,' p. 93) and other writers have supposed—identical with the rubeola of German authors. Probably the papules described by Vogel and Borsieri as *ardentes et prurientes*, and named Essera Vogelii, were of the same nature. Essera is defined by Blanchard ('Lex. Med.,' ed. 1702) as *tubercula parva, ad rubrum vergentia, duruscula, cum insigno pruritu subito universum corpus occupantia.*

Protection.—Second attacks are rare, probably rarer than in the case of true measles; statements to the opposite effect no doubt refer to epidemic roseola, not to rubeola. It does not protect from measles or from scarlatina. Among sixty-three cases of rubeola seen by Dr Dukes, thirty-nine had previously had measles. Among thirty cases observed by Dr Cheadle, twenty-two had had measles, and ten of these cases had been under his own care. There seems no reason to suppose that measles predisposes to rubeola, but measles attacks, as a rule, younger, and rubeola older children. There are, however, several instances of an epidemic of rubeola following one of measles.

Prognosis.—Most authors agree in saying that in epidemics much more severe cases than the rest may occur, and that death may occasionally happen. If, however, we exclude the description by Paterson, these cases must be extremely rare. A favourable prognosis may therefore be given.

No special *treatment* is necessary. The patient need not in many cases be confined to bed after the nature of the complaint is clear, but he should be secluded from others for a fortnight if infection is to be prevented.

SMALLPOX*

"That day that the Friends on both sides met to conclude the Marriage, she fell sick of the Smallpox, which was in many ways a great trial upon him: first her Life was allmost in desperate hazard, and then the Disease (for the present) made her the most deform'd person that could be seene, for a great while after she recover'd; yett he was nothing troubled at it, but married her as soon as she was able to quitt her chamber, when the Priest and all that saw her were affrighted to looke on her. But God recompenc'd his justice and constancy by restoring her as well as before."—*Life of Col. Hutchinson.*

Name and history—Contagion and spread—Incubation—Onset—Early rashes—Specific eruption—Varieties of the Exanthem—Course and symptoms—Discrete, confluent, and modified Smallpox—Complications and sequelæ—Prognosis and treatment.

VACCINIA—*Inoculation—Introduction of vaccination—Course of the eruption—Its protective power—Its drawbacks—Its relation to Variola.*

THIS terrible disease—after the disappearance of the plague and before the introduction of vaccination, the most fatal of all epidemics—was unknown to the ancients. It was first described by the Arabian physician Rhazes about 900 A.D., under the name *Jadari*, translated into λοιμική, i. e. the pestilential eruption, by the Greeks, but was long regarded as a more severe kind of measles.

It is probable that some of the pestilences of the later Roman Empire and of mediæval Europe were really epidemic Variola. As the knowledge derived from the Arabian writers by Greek and Jewish physicians became diffused, the more severe and dangerous disorder was discriminated from measles, but even when, in the sixteenth century, smallpox was generally recognised, the two were often confounded together, and so late as 1660 Pepys speaks of measles as "the same disease" as the smallpox ('Diary,' January 11th, 1660–1).

Variola appeared in America soon after its discovery, and was terribly destructive among the natives. It is almost as much so in Central Africa now.

In China long before the Christian era Variola was well known, and is described in books still extant.

Origin.—Smallpox is in some respects the most typical of the class of exanthemata. Its infectious character has never been doubted, and its virus is as active as that of typhus and almost as persistent as that of scarlatina. It resides in the serum and pus of the exanthem, and can be preserved in the powdered crust of the skin. It has been proved by

* *Synonyms.*—Variola.—*Scottice* the Pocks, *Fr.* la petite Vérole, *Germ.* Blattern, Menschenpocken, *It.* Vajuolo, *Mod. Gr.* Εὐλογία, a euphemistic term.

The English word refers to the pockets or little pocks, pokes, or bags in which the matter is contained, and denotes the pustular form of the eruption. It also marks the distinction between this and the still more dreaded Great Pox, *i. e.* Syphilis. The low-Latin word *variola* is a diminutive formed from *varus* (with a short *a*, although this did not prevent a Ciceronian pun between it and *varius*), a pustule or pimple, used as a translation of the Greek term, ἴονθος. The word variola first occurs in this sense in the sixth century. In older medical literature the plural form *variolæ* is used: referring, like "smallpox" and "measles," to the individual little *vari* or "pushes" of the eruption.

filtration to be particulate; but no distinctive micrococci have been yet discovered, so that its bacterial character is an inference from analogy, and not a certainty. The disease may be spread without actual contact with a patient by inhaling dried-up secretion or by fomites which have been contaminated with the pus, and probably by the air at a distance. The blood does not appear to be contagious, nor the excretions.

There are no decided predisposing causes of smallpox. It attacks persons of every age and race, and is equally destructive in every climate. It has, however, been remarked that children and pregnant and puerperal women are particularly liable to take it severely.

Variola can be transmitted to many of the lower animals by inoculation with the pus, but is a much less fatal disease than in man, and does not spread. Many pathologists, however, believe that vaccinia in cows and one kind of the affection known as "grease" in horses is modified variola.

The incubation of smallpox is, as a rule, twelve days. On the thirteenth day from that on which the contagion entered the patient's body, he is seized with symptoms of fever. Most writers allow that the interval may sometimes be longer; Bristowe extends it in exceptional cases to sixteen days; but Marson affirms that he has never found the eruption fail to appear in fourteen days after infection. He admits, however, that the incubation is sometimes shortened by three or four days, and Curschmann alludes to one instance in which it did not last more than five days. Zülzer believes that in the hæmorrhagic form of variola it is constantly from six to eight days. When variola is transmitted by direct inoculation the period of incubation is only nine or ten days.

During this period the patient generally feels well; but occasionally he complains from the very first of a vague malaise, with gastric disturbance, headache, and giddiness, and towards the end there may be a little pharyngeal catarrh, with reddening of the uvula and tonsils.

Prodromal stage.—This usually sets in with a severe rigor or with a succession of slight chills. The temperature at once begins to rise, and may reach 102° to 104° within twenty-four hours, and 105° or even 107° by the second day (*fièvre d'invasion*). In some cases the patient becomes rapidly prostrate, and totters if he attempts to stand. Curschmann remarks that whereas a working man attacked with enteric fever will often come on foot to the hospital at a time when his temperature is already high, one who has smallpox must be carried. Such a patient, while he is out of bed, has cold limbs, a pale sunken countenance, and a small pulse; so that he is hardly to be recognised a few hours later, when he has become warm, and when his face is red and turgid. The pulse is much accelerated, varying from 100 to 120 in men, while in women it may reach 130 or 140, and in children 160. The breathing is quick, short, and laboured. The skin is generally dry, but sometimes moist or even sweating. Some medical men, among whom was the late Mr Stocker, believe that it already emits a peculiar odour; and it is said that the late Dr Guy Babington when taking in patients to the hospital could recognise any cases of variola by the smell. The breath is fœtid, and the tongue is often very foul. Anorexia and thirst are present. The patient almost always complains of pain across the forehead or over the whole head; and this is sometimes intense. Children are not infrequently attacked by epileptiform convulsions; or they may become

delirious or comatose. They often have diarrhœa; but in adults constipation is usual. In the more severe cases enlargement of the spleen may be detected.

So far there is little to distinguish the early period of variola from that of other fevers. A more characteristic symptom is *vomiting*, attended with violent retching and pain at the epigastrium, and sometimes so severe and persistent that a case has been sent up to hospital as one of ileus. Another symptom, still more characteristic, is *pain in the sacrum and loins*. This, however, is not constant; Curschmann says it occurred in rather more than half of his cases. It appears to be most frequent in severe cases. Women are apt to suppose that it merely indicates the approach of menstruation; or, if they are pregnant, that labour is about to set in. And, as a matter of fact, the catamenia do frequently appear during this stage; sometimes prematurely, but often in their regular course. In men the pain in the loins is likely to be mistaken for lumbago.

Another set of symptoms, which are of importance because they may cause the disease to be mistaken for measles, are those of common *catarrh*—sneezing, epistaxis, intolerance of light, lacrymation, sore-throat, and hoarseness. The tonsils and the palate may be seen to be reddened.

Lastly, the initial stage of smallpox is occasionally attended with one or other of two distinct forms of cutaneous rash, which differ in their characters and still more in their significance.

Early roseola.—One of them may be described as *roseola variolosa*, the name employed long ago by Rayer, and in 1853 by Eimer. Morton, writing in 1718, records it in one of his cases (No. xxxviii), and calls it an early rash resembling scarlatina. Until recently most observers regarded the presence of this remarkable rash as a proof that one of the other exanthemata was present in addition to variola. Reinhold, in 1840, seems to have originally propounded in express terms the doctrine that it is a preliminary symptom of smallpox alone. In this country Dr Wilks drew attention to it in the 'Guy's Hospital Reports' for 1857 and for 1861. Watson also mentions it in 1857. But Simon, of Hamburg, is the writer who has most fully described it, and has recorded the largest number of cases. It is more common in some epidemics than in others. As a rule it comes out on the second or the third day; but sometimes it immediately follows the initial rigor, and occasionally is the earliest sign that anything is amiss with the patient. It may last a day or two, but sometimes is over in a few hours.

There are several varieties of this early roseola. One is maculated, and is more or less like measles; it may come out all over the body, perhaps appearing first upon the face. Another is an evenly diffused red blush, resembling scarlet fever, but (according to Simon) darker and of a more purplish tint. This often has a characteristic distribution, which was pointed out by Hebra: it is limited to a triangle having for the base a horizontal line drawn across the abdomen about the level of the umbilicus between the two iliac spines, while the apex is formed by the contact of the two thighs. It may also be visible in the axillæ, and on the adjacent parts of the upper arms and of the chest. On the limbs it may affect the extensor surfaces of the elbows and of the knees, the backs of the hands and fingers as far as the first phalangeal joints, and the back of each foot in a line corresponding with the course of the extensor tendon of the great toe. Its distribution is so characteristic that it enabled the writer several years ago

to diagnose a case in which there was no other reason to suspect smallpox. Even if no other eruption should afterwards develop itself, one ought probably still to maintain the diagnosis of variola, for Simon has recorded an instance of this kind in which the disease aborted, notwithstanding that its real nature was proved by the patient's sister suffering from an attack of variola at the same time. Sometimes the seat of *roseola variolosa* is irregular. We have in our museum at Guy's Hospital models of a case in which it affected only the flexor surfaces of the forearms; and in women it may be limited to the skin about the nipples. Another variety resembles urticaria, while in many cases it assumes a petechial form, and leaves green or brownish stains after it has faded. A point of importance is that, even when it thus becomes hæmorrhagic, the prognosis need not be unfavourable. Hebra and Trousseau seem to have independently remarked that the parts affected by *roseola variolosa* afterwards remain free from the proper smallpox rash; and most subsequent observers have confirmed this statement.

Early purpura.—Very different is the second form of initial eruption, which in fact marks the most fatal of all the varieties of smallpox, the *Variolæ nigræ* of older writers, also known as *Purpura variolosa*, and *Malignant* or *Hæmorrhagic smallpox*.

After the usual early symptoms have been present during from eighteen to thirty-six hours there appears on the trunk and the limbs a diffused scarlet redness, which at first can be made to disappear by pressure with the finger. This soon becomes the seat of extensive effusions of blood, in spots and patches of all sizes and shapes. Large black rings now form round the eyes, and the conjunctivæ are ecchymosed: this, according to Marson, is often seen very early in the case, and is always a most dangerous symptom. The breath has a horrible fœtor, from the presence of a "diphtheritic" affection of the throat. Hæmorrhages may occur from any or all of the mucous surfaces. Bloody liquids are coughed up or vomited, or discharged from the uterus or the bladder; or there may be epistaxis, or a sanguineous flow from the eyes or the ears. The urine is extremely fœtid, and it is albuminous even when it contains no blood. The patient generally complains of severe pain at the præcordia, and suffers severely from vomiting. Yet, according to Curschmann, the temperature is seldom over 104° until just before the fatal termination. Both he and Marson remark that consciousness is generally retained almost to the very last; "few patients are so fortunate as to become quickly delirious or comatose." Anæsthesia or hyperæsthesia of certain parts of the surface, and paralytic affections of the limbs, are said to have been observed by Zülzer. Before death the whole body becomes black or of a leaden grey colour. According to Marson, the smallpox eruption is nearly always confluent in cases of this kind; but they often end too rapidly for this stage to be reached. Dr Fagge, however, recorded two or three instances in which, although the disease was prolonged for several days, not even papules could be discovered. The first of these cases occurred in the clinical ward of Guy's Hospital; the patient lived several days, and as no sign of a proper smallpox eruption could be detected, it was supposed not to be an example of *purpura variolosa;* but a few days afterwards the clinical clerk who watched the patient fell ill with a mild form of smallpox. It has often been remarked that strong muscular men are particularly apt to be attacked with hæmorrhagic smallpox; but it is also seen in drunkards, in women recently confined, and in those who are pregnant.

Slight and abortive cases.—Occasionally the symptoms during the pro-

dromal stage are very slightly marked, or even absent; the smallpox eruption then appears after a few hours' malaise, or is the first sign that the patient is ill. In such cases the disease itself is always very mild; so that Trousseau is not right in saying that the longer the exanthem is postponed the less serious is the attack.

Unlike a slight initial stage, one which is severe is no guide as to the ultimate progress of the case. In women and in children it often happens that the most alarming symptoms are present during the first day or two, notwithstanding that the rest of the disease is to be of a mild character. The most extreme instances of this are afforded by a form of smallpox which was long ago described by Sydenham as *Febris variolosa*, and by de Haen as *Variolæ sine variolis*. After a well-marked initial stage the disease aborts, and the patient is well in three, four, or six days at the latest.

The exanthem.—As a rule, the *third* day is that on which the characteristic eruption of variola appears; but in children it is often the second day. Sometimes nothing is to be seen until the fourth day, and then the prognosis is comparatively favourable. A still further postponement seems to occur only when there is some complication, as in a patient of Trousseau's who had choleraic symptoms.*

The proper variolous exanthem is first papular, then vesicular, and finally pustular. The papule is round and smooth; at first it may be scarcely redder than the rest of the skin; and as it is hard, like a small shot, it can often be felt better than it can be seen. But after twenty-four hours it is always decidedly reddened, besides having increased in size. It depends upon a definite change in the superficial and middle cells of the rete mucosum, which from the very commencement of the morbid process are swollen and opaque. Liquid exudation quickly takes place, so that by the end of two days the horny layer of the epidermis is raised to form a minute conical vesicle. By the fourth or fifth day of the eruption (seventh or eighth of the disease) the vesicle is generally as large as a split pea, hemispherical in form, and opaline in appearance. As a rule, the *pock*, as it is termed, has a central depression or umbilicus. The origin of this has been much discussed; it generally seems to depend upon the fact that the original papule was developed round the mouth of a hair-sac, or else round that of a sweat-gland, either of which structures may afterwards form a *retinaculum*, tying down the roof of the vesicle in the middle. Rindfleisch gives a drawing of a preparation in which a sudoriparous duct is plainly seen in this relation to the pock, and he says that he has many such specimens in his possession. However, it would seem that this explanation is not always applicable, since the pock does not necessarily bear a definite relation to any of the canals which traverse the cuticle. In all probability a similar function may be discharged by one of many other bands which cross the upper part of every vesicle in a direction more or less vertical, dividing it into a number of separate chambers. This *loculated* character of the pock attracted notice long before its nature was understood; it affords the reason why only a small part of the fluid is evacuated when a needle is introduced into the roof at a single spot. But the idea of the older observers was that the septa between the chambers were new formations, consisting of fibrin. Sir

* Among thirty-eight cases of Variola recorded by Dr Richard Morton in the City of London two hundred years ago (1670—94) the eruption appeared on the third day in twenty-six, on the fourth in seven, and on the second in five.

Thomas Watson, for instance, speaks of a "central whitish disc," consisting of "several little cells;" and this, he says, may by careful dissection be taken out entire with the "lymph" which it contains, even when the rest of the fluid in the pock has become yellow and purulent. Auspitz and Basch, however, showed several years ago that all the septa in question are in reality formed out of the original cells of the rete mucosum, small bundles of which cohere together, and become stretched out into filaments and bands, as the exudation accumulates around them. In this fluid leucocytes are present in small numbers from the very first; they go on increasing, and thus transparent serum gradually passes into opaque pus; the change is complete in about six or seven days from the first appearance of the papule,—that is, in the earliest part of the eruption, by the ninth or tenth day of the disease. The pustule, when at its height, is often hemispherical, the umbilicus having disappeared in consequence of the rupture of the retinaculum which formed it.

But while the roof and the cavity of the pock are thus being developed out of epidermic structures, a morbid process is at the same time going on more or less actively in its floor, which consists of the papillary layer of the cutis, with at least the lowest cylindrical stratum of the rete Malpighii. Whether a swollen state of the papillæ has any share in the formation of the original papule appears to be doubtful; but there is no doubt that its redness is due to their hyperæmia; and (according to Bärensprung) this extends down through the whole thickness of the skin. The exudation which fills the vesicle, and afterwards the pustule, is necessarily derived from these vascular tissues. But Curschmann says that, so far from the papillæ being always enlarged at this stage, they are often rather flattened by the pressure to which they are subjected. In some cases, however, they become the seat of an infiltration of leucocytes, which is so intense that it obliterates their blood-vessels, and, indeed, destroys their structure completely, converting them into a white or ash-grey substance. German histologists, in accordance with their usual terminology, describe this form of pock as *diphtheritic* (*vide supra*, p. 52). The contrast is the greater because the surrounding skin is of a bright red colour for a considerable distance, making what is termed the *halo* or *areola*. The infiltration of leucocytes into the floor of the diphtheritic pock may extend to a varying depth in the derma, or even through it into the looser tissue beneath. Rindfleisch gives a drawing from an injected preparation, in which the affected area had failed to receive any of the colouring matter.

Many of the pustules of smallpox undergo destruction almost as soon as they are fully formed. They break, or are ruptured, giving exit to a honey-like matter, which collects in drops upon the face or other exposed parts of the patient's skin, and saturates his shirt, his pillow, and his sheets. Others, however, remain uninjured, and ultimately dry up without discharging their contents. First a yellow-brown spot appears in the roof of the pock; this sinks in, so as somewhat to resemble the earlier umbilicus; gradually it enlarges and extends to the periphery. The process of desiccation, both in ruptured pustules and in those which are entire, begins about eight or nine days after their first appearance in a papular form. The crusts vary in colour from yellow to brown, or even black, as more or less blood is mixed with the pus of which they are formed. It is now that the extent to which the cutis vera has been involved in the inflammation affects the result. If it has escaped, the crusts fall off in four or five days (about the

fifteenth or sixteenth day of the disease), leaving purple-red stains, but little or no permanent cicatrisation. But if pus-cells have infiltrated the papillæ, or the whole thickness of the skin, these structures, to whatever depth they may have been affected, slough away and become detached, as shreds, adhering to the under surface of the crusts. Their separation takes longer, and may not begin until the eighteenth or twentieth day. Moreover, when it occurs, granulating surfaces are exposed which may take a considerable time to heal. The resulting cicatrices are for a time of a brown colour, but ultimately they become whiter than the skin around them. They may either be so faint as to be scarcely perceptible, or more or less deep and pitted. It often is not until many months after recovery from the disease that they become depressed below the surface to the full extent.

Distribution.—So much for the appearance, structure, and course of the individual pocks of variola; the locality and range of the eruption will now be considered. Like the rest of the exanthemata, it does not develop itself over the whole body at once; it appears first upon the face and scalp, especially on the forehead and about the eyes, the nose, and the upper lip. A few hours afterwards it is to be seen upon the trunk and the arms. Marson mentions the wrists as among the earliest parts affected, and says that on the legs and the feet it is generally two days later than elsewhere. He also lays stress on the fact that the papules come out "in threes and fives, forming crescents," or even a complete circle if two crescents happen to coalesce. During the first day or two fresh spots keep appearing, even on those parts which are already more or less thickly covered; but by the end of this time the eruption is complete, for even if a few more should afterwards show themselves they soon abort and die away. A curious circumstance is that smallpox specially affects any parts of the skin which may happen to have been recently irritated; the red patch from a mustard plaster applied during the incubation or shortly before will present many more pocks than the regions adjacent.

Certain *mucous membranes* take part in the eruption of smallpox, but not in quite the same way as the skin. There first appear raised spots, whitish or grey in colour, contrasting with the reddened state of the surface around them; but these quickly pass into excoriations. They are sometimes present in large numbers on the inside of the lips and on the cheeks; sometimes they rather affect the tonsils and the palate, which may then become greatly swollen and the seat of deep phlegmonous inflammation, ending in abscess. On the other hand, the tongue very seldom presents any traces of vesicles, but is sometimes enormously enlarged, protruding from the mouth, rendering the patient unable to close his jaws, and apparently helping to bring about a fatal issue. The air-passages are said to show more or less distinct pustules as low as the bifurcation of the trachea, or even (according to Wagner) down to bronchia of the second or third order; there may also be deep ulcers in the larynx, with perichondritis and necrosis of cartilages, and œdema of the aryepiglottidean folds. In the alimentary canal nothing resembling a pock can be seen below the upper part of the œsophagus, except perhaps in the rectum close to the anus, or at the entrance of the vagina. Marson speaks of twenty-six cases at the Smallpox Hospital, out of a total of over fifteen thousand, in which the conjunctiva showed a single pustule, which was generally situated midway between the cornea and the internal canthus. It did not in any way affect the sight or lead to any ill result.

Varieties in the eruptive stage.—Roughly speaking, the severity of variola depends upon the number of the pustules; and in the relation of the pustules to one another we have a criterion which, while it is itself based upon their number, affords a natural division of the most marked kind. Whenever they are so crowded that they run together the disease is said to be *confluent.* This may either be the case over the whole of the body, or only over certain parts of it, or even on but a single region: this is always the face, since the eruption is never more abundant than upon the face. On the other hand, if the pustules remain everywhere distinct from one another the smallpox is described as *discrete.* Between the two forms the state of the face alone decides; and there is seldom any difficulty in calling a case either confluent or discrete. Watson, however, speaks of some cases in which the pustules stand just thick enough to touch one another without coalescing, and would then call the disease *cohering;* and Trousseau alludes to instanccs in which a few isolated patches are found confluent, but which he would term discrete.

In ordinary discrete, as well as in confluent smallpox, the pustules run through all their stages, unless, indeed, the disease should happen to be cut short by the patient's death. But there is a third variety, consisting partly of discrete and partly of confluent cases, which is characterised by the premature subsidence or abortion of the eruption. For this, unfortunately, there is no satisfactory name. German writers* describe it as "*variolois,*" a word etymologically misleading as well as barbarous; since it is not "like variola," but is true, though modified variola, and capable of generating the severer forms by contagion. In this country it is generally termed *modified smallpox,* because it is comparatively seldom seen except in persons who have already passed through a former attack, or who have been vaccinated. But it is important to know that variola occasionally passes off in exactly the same manner in a patient who is altogether unprotected.

1. In *discrete smallpox* the eruption presents in their most typical forms the characters which have been described as belonging to the individual pustules. Its amount, of course, varies infinitely in different cases, from a few spots that can almost be counted on the fingers up to many thousands. At the time when they are acquiring their areola there is often a considerable degree of swelling of the surrounding parts, especially when the subcutaneous tissue is loose. Even three or four pustules upon the eyelids may cause them to be puffed out like bladders, so that on the ninth and tenth days the patient may be unable to open his eyes. Trousseau cites a case of Van Swieten's in which a single pustule on the prepuce produced phymosis and great difficulty in micturition. He remarks that the absence of a corresponding degree of tumefaction of the rest of the face renders the swelling of the eyelids more conspicuous in some cases of discrete smallpox than in the confluent variety of the disease. At about the same time the pustules first begin to be painful.

As regards the general symptoms of discrete smallpox, the first thing to

* Strictly speaking I think that this is not quite correct. It is true that German writers give *variola modificata seu mitigata* as a synonym for their "*variolois;*" but in practice they confine the use of the latter term to cases of a certain moderate degree of severity, and apply it to all such cases, whatever may be the course of the individual pustules. Thus Curschmann speaks of *variolois* as sometimes leading to destruction of the papilla and to the formation of deep cicatrices, "so that what distinguishes the case from one of *variola vera* is merely the very much smaller number of pustules." We should call such a case one of very mild discrete *unmodified* smallpox. On the other hand, I do not find German writers mentioning under *variolois* the examples of modified confluent smallpox which will presently be described.—C. H. F.

be noticed is that as soon as the eruption has fairly begun to develop itself, the fever which has existed during the initial stage subsides, and the temperature falls within thirty-six hours to normal, or even lower. Its decline is not always quite continuous, being perhaps interrupted by a slight evening exacerbation. At the same time the pain in the back and the sickness disappear, and the patient often feels perfectly well, with as good an appetite as when in health. This lull in the symptoms commonly lasts for three days; at the end of it he is, in all cases except those in which there are but very few pustules, again attacked with shivering and with febrile disturbance, which is known, as the *secondary fever*, or the *suppurative fever*, or the *fever of maturation*. The date at which this sets in seems to be differently stated by writers; Trousseau puts it at the seventh or eighth day of the disease, Watson at the eleventh. It is generally remittent in type, the daily variations amounting to one or two degrees Fahr. The height to which the thermometer now rises varies with the extent of the inflammation in the cutaneous tissues, and therefore roughly with the number of the pustules; even in severe cases it is seldom above 102° or 103°. The pulse is quickened, being at from 110 to 120. The patient at the same time complains of headache, and is restless and sleepless. He is not unfrequently delirious, especially during the first night or two.

It must not be supposed that discrete smallpox is always unattended with danger. Trousseau relates the case of a girl, aged twenty-one, who had passed through a remarkably mild attack, but who was one evening suddenly seized with cerebral symptoms and difficulty of breathing, and in an hour she was dead; and he remarks that when this form of the disease does prove fatal, death occurs at an earlier date than in the confluent form—namely, about the eighth or the ninth day. In ordinary cases of discrete smallpox the fever lasts about three weeks, or even less, and the crusts have fallen by the time that normal temperature is regained.

2. In *confluent smallpox* the eruption necessarily fails to some extent to present its typical characters, at least upon those parts of the body where an actual fusion of its elements has taken place. Even before any definite papules can be recognised, there is often a diffused redness of the face, which in itself could hardly be distinguished from the rash of measles. Watson mentions a case in which the appearances of urticaria, with its characteristic sensations, were at the outset so intermingled with the papules of variola that for twenty-four hours he doubted which of the two diseases was developing itself; and in other instances smallpox has been mistaken for erysipelas. Trousseau remarks that even where there are, in fact, multitudes of papules, the complete absence of intervals between them may render one almost unable to detect any unevenness of the surface by passing the hand over the patient's forehead or cheek. The papules are always smaller than in the discrete form; they coalesce so as to form the most irregular figures and patterns. At a very early period a milky fluid collects in their summits, giving rise to minute flat vesicles. The whole of the face has then a whitish-yellow colour, and its appearance is exactly like that of a mask of parchment, to which Morton, in his 'Pyretologia' (1718, Case xxxviii), long ago compared it. By this time, however, there is already a good deal of swelling, and it goes on increasing up to the ninth day of the disease, and until the features are so altered that it is impossible for the patient to be recognised by his nearest relations. The parts about the ears and the sides of the neck become enormously bloated; the eyelids cannot be opened. This

condition is very painful, and the scalp is often so tender that the pressure of the head upon the pillow can hardly be borne.

Somewhat later, about the eleventh or twelfth day, the hands and the feet become red, swollen, and painful. Trousseau, following certain of the old writers, attached a high prognostic value to this symptom; according to him its absence is almost always followed by death.

The *mucous membranes* generally suffer severely in confluent smallpox. The interior of the mouth not only presents the eruption already described, but the fauces may become covered with a diphtheritic membrane. Laryngitis often renders the voice very hoarse, and it sometimes causes a sudden fit of suffocation, which proves fatal in a few seconds before anything can be done to relieve it. Trousseau mentions three cases of this kind, in each of which death seems to have occurred unexpectedly on the eighth day of an illness that had previously run a normal course.

Another complication, perhaps due to extension of inflammation to the parotid gland, is *salivation*. Trousseau speaks of this as a characteristic feature of confluent smallpox. It begins, he says, about the fourth or fifth day, and goes on increasing until by the ninth or the tenth day one or two quarts may run from the patient's mouth within the twenty-four hours. Even during sleep there is a constant flow of saliva.

Again, ophthalmia is of frequent occurrence, which (unlike the harmless discrete pustules of the conjunctivæ) is often attended with sloughing of the cornea, and leads to permanent blindness.

From the very commencement of the eruptive period, the general symptoms of confluent smallpox run a course which differs from that of the discrete form of the disease. Instead of the temperature falling when the papules come out, it remains at 103° or 104°. There is often violent *delirium*, even during the daytime. It may be quite impossible to keep the patient in bed, except by tying him down with a folded sheet across the chest. If free, he must be most carefully watched, or he is very likely to throw himself out of a window or over the stairs, or to cut his throat with a razor. In those who have been intemperate, the nervous disturbance often assumes the form of delirium tremens.

Convulsions are a frequent and often a very grave complication.

Retching and vomiting often run on throughout this period of the disease; and *diarrhœa* is obstinate and troublesome. The urine contains albumen in a large number of cases.

When suppuration is established, there is a further rise of temperature. Indeed, it becomes higher than in the corresponding stage of discrete smallpox, although, from the patient having all along been feverish, the development of a fever of maturation is less conspicuous.

This secondary fever is the most dangerous period of variola. Few patients die before the eleventh day; the most fatal days are the twelfth, the thirteenth, and the fourteenth. Towards the last there is generally coma; sometimes hyperpyrexia is present, as in a case of which Wunderlich gives a chart, and in which, before its termination on the eleventh day, the thermometer registered 109°. In many instances the immediate cause of death is bronchitis, pneumonia, pleurisy, or pericarditis. Even under the most favourable circumstances the fever runs on for at least ten days longer. Not infrequently, during the third week, the patient falls into a typhoid condition, with sordes, a dry brown tongue, muttering delirium, and subsultus; and he is then very likely to die of exhaustion.

When recovery is to take place, whether from the discrete or the confluent form of the disease, the redness and the swelling of the face subside, as the pustules undergo conversion into crusts. The pain from which the patient has been suffering passes off, but only to be followed by the most intolerable itching. His fever also declines more or less rapidly, being now proportionate to the amount of inflammatory action still going on. He regains his appetite, and becomes once more able to sleep. He opens his eyes, and gradually his features begin to reassume their natural outlines. At the time when the crusts are falling off, or a little later, he generally loses almost all his hair, and if the deeper layers of the skin of the scalp have been involved in the morbid processes there is always reason to fear that permanent atrophy of the hair-sacs may result.

The confluent variety of smallpox usually lasts about four weeks before the fever subsides.

A minor variety of smallpox, which sometimes occurs in confluent cases, is characterised by the occurrence of hæmorrhage into the pustules. This must not be confounded with the "hæmorrhagic variola," which proves fatal at an early period before the proper exanthem has come out (*supra*, p. 202.) By way of distinction Curschmann calls it *variola hæmorrhagica pustulosa*. As a rule, those pustules which are seated upon the lower limbs are the first to show a purple colour. Bleeding presently takes place from the nose, kidneys, intestines, and other mucous surfaces. In women menstruation sets in, or abortion occurs if they are pregnant. The gums become spongy and bleed, as in scorbutus; the fauces show a kind of "diphtheritic" affection, which is attended with a terrible fœtor. The constitutional symptoms are in most respects severe; but although the pulse is very rapid the temperature during the eruptive stage is seldom above 102°, and it not rarely falls to 95°, or even lower, before the patient's death. Curschmann says that this variety of smallpox occurs chiefly in persons over forty years of age, and in such as were previously out of health. He describes it as being almost always fatal; but remarks that in patients who have, in their delirium, got out of bed and walked about during the early part of the eruptive stage, the pustules on the legs may become filled with blood, without the case being particularly serious. A few petechiæ on any part of the surface are not a dangerous symptom.

Another variety of the smallpox exanthem was described by Marson as *corymbose*. His account of it will be found in Reynolds's 'System of Medicine,' but no one appears to have confirmed his observations.

3. In *modified smallpox*—which, as we have seen, is not exclusively confined to protected persons—the course of the eruption is much less regular than in the ordinary forms of the disease, whether discrete or confluent. During the initial stage, however, no distinction can be drawn between it and them: no doubt there is a larger proportion of cases in which that stage is but little marked; but in some instances, at least, it lasts the usual time, and is attended with severe symptoms. But when the papules begin to appear, it is said that the characteristic irregularity is often shown by their being visible upon the trunk or elsewhere before there are any of them on the face; and it is also said that the period during which fresh ones develop themselves is variable, the number being sometimes complete in a few hours, while in other cases they keep coming out even when those which were first formed have already become pustules. And what appears to be still more indicative of this variety of smallpox is the course of the fever at

the commencement of the eruptive stage. The temperature falls, as in unmodified discrete variola, but with still greater rapidity, and without any interruption in its downward path, so that in less than twenty-four hours it is normal. Trousseau and others, however, speak of confluent smallpox running its normal course for ten or twelve days, and then suddenly subsiding, so as to show that it really belongs to the modified form of the disease.

It is thus evident that no definite period can be fixed at which the modified character of a given case of smallpox first becomes apparent. Sometimes the eruption dies away before it has passed out of the papular stage. Sometimes the papules undergo a partial conversion into vesicles, which then rapidly dry up. A special modification of this variety of the affection has long been known as the "horn-pox" (*variola verrucosa*); but writers by no means agree in their descriptions of it, for while Trousseau speaks of the vesicles as drying up and leaving in their places small, hard, corneous projections, which fall by a sort of desquamation between the tenth and the fifteenth days, Curschmann says that after the scabs have become detached, the solid bases of the pocks remain for a considerable length of time as warty elevations, especially on the face, to which they give an ugly appearance.

Again, in yet other cases of modified smallpox, the vesicles pass on into pustules. The change then appears to take place unusually rapidly, and the pustules themselves are often extremely small, and probably never reach so great a size as that to which they may attain in the unmodified forms of the disease.

Complications and results.—The complications of smallpox, besides those already mentioned, are few. Bronchitis is frequent, and hypostatic pneumonia not unknown; pleurisy, when it occurs, is apt to lead to empyema; and œdema of the larynx has occasionally proved fatal. Salivation is frequent and distressing. The febrile albuminuria rarely leads to subsequent nephritis.

The *sequelæ*, beside the pitting, are chiefly various forms of local suppuration, like those which follow enteric and scarlet fevers: abscesses in the skin and deeper organs, furunculi and ecthyma, local gangrene and phlegmonous erysipelas. In severe cases the cornea may ulcerate, and the eye be lost.

Convalescence is, however, usually rapid, and the health and strength are not impaired as after enteric fever.

The *protection* afforded by smallpox is probably the most complete known. Relapses never follow, and although second attacks undoubtedly occur, they are more rare than in the case of typhus, measles or scarlatina.

Prognosis.—The points upon which this depends have been already indicated. They are, first, the number and quality of *vaccination marks*. The statistics of the Smallpox Hospital for twenty years show that where four distinct and pitted scars were present the mortality was only one in two hundred; where three equally good were found, less than 1 per cent.; where three indifferent marks, more than 3 per cent. Two good marks kept the mortality down to 2·3 per cent., two poor ones only to 8 per cent. With one good mark, less than 4 per cent. of the patients died, and with one indifferent mark nearly 12 per cent. At the same hospital the mortality among unvaccinated patients generally was 37 per cent. (Marson).

The second indication for prognosis is the abundance and the character of the *exanthem*. Dr Marson's statistics give the mortality among 2654 of unvaccinated patients as 4 per cent. in cases of discrete variola; 8 per cent. in cases of semi-confluent, including coherent, variola; and 50 per cent. in cases of confluent variola. A purpuric eruption is of most serious omen—most so when it precedes the true exanthem; hæmorrhagic pustular smallpox is also extremely dangerous, but not so dangerous as hæmorrhage in the papular or vesicular stage.

The most favourable *age* is from eight or ten to twenty; even then about 25 per cent. of unprotected cases are fatal. More than half the unvaccinated patients above thirty years old die, and of those above sixty nearly 80 per cent. To children under five smallpox is as fatal as to adults between thirty and forty; about half of those who are attacked die. Marson observed that children who grind their teeth hardly ever recover.

Previous drinking habits, delirium, convulsions, and want of sleep are indicative of danger.

Pregnancy is usually a fatal complication; abortion usually takes place, and the mother dies soon after. Cases, however, are recorded in which both the mother and the child have survived.

Among sixty-seven cases recorded by Morton (before inoculation or vaccination was known), all but two being under thirty years of age, thirty-eight recovered and twenty-nine died—a mortality of 43 per cent. Of four cases complicated by abortion, only two were fatal.

Treatment.—There is no special means of curing smallpox apart from treatment of the fever and of the local complications. The most rigid isolation is of course necessary for the sake of others, and all who come in contact with the patient should be revaccinated. Free ventilation and the utmost cleanliness are the first essentials. Diarrhœa should be checked. Laudanum and morphia are extremely valuable as hypnotics. Ammonia and senega are needed for bronchitis, and stimulants during the suppurative stage, especially when boils or abscesses appear.

Constant watching is necessary, in order to prevent the patient escaping from the sick-room or doing himself an injury in his delirium. But Dr Collie recommends that a restless patient should be allowed to get out of bed, and even to sit by the fire, if he persists in the attempt.

In order to ease the irritation of the skin and prevent scratching, as well as to soothe the fever, warm or lukewarm baths of about 100° or about 85° Fahr. are recommended, followed by inunction with oil or vaseline. The face should be covered with a thick layer of lead or zinc ointment, and the pustules should be pricked as soon as formed, in order to diminish scarring.

Vaccination in unprotected persons exposed to contagion is imperative; and even if performed after the first symptoms of the disease have appeared, it probably has some effect in diminishing its severity.

But the true treatment for smallpox is prophylactic, and will next be considered.

VACCINIA. *Syn.* Cow-pox.—The terrible mortality from unmodified smallpox, and the scarcely less terrible results it left behind—the scarred and hideous features, the sight injured or lost, permanent deafness, and other disastrous results—can only be appreciated by those familiar with the general as well as the medical literature of the last century. Treatment of

the disease had been much improved by Sydenham, but its ravages were still almost unchecked until the introduction of the practice of *Inoculation*. This has been carried on in China from time immemorial, but it is not known how it was introduced into Turkey. An account of inoculation as a prophylactic for ordinary smallpox was first published in the 'Philosophical Transactions' for 1714, but it became popular seven years later by means of the letters and example of Lady Mary Wortley Montagu, the wife of the English ambassador at Constantinople. By inoculation with the lymph from a variolous vesicle the disease is reproduced with a shorter incubation period, with far less severe symptoms, and with a far smaller mortality than when contracted in the ordinary way.

Variola, however, thus produced was still variola, and as contagious as ever, so that the effect of inoculation was to make cases of smallpox more numerous, though generally milder. Thus, although the mortality was reckoned at only 3 *per mille*, the total deaths from smallpox were increased. The Smallpox and Inoculation Hospital was founded in 1746, and inoculation was practised there down to 1822, but after 1840 it was prohibited by Act of Parliament. The operation was performed in China by putting variolous crusts into the nostrils, but in Europe in exactly the same way as vaccination, except that the lymph was variolous instead of vaccine.

The practice of *vaccination*—the greatest achievement of medicine—was the fruit of the scientific temper and indomitable perseverance of the illustrious Edward Jenner. He observed that the milkmaids in the great dairy farms of Gloucestershire were subject to a particular eruption of the fingers, which was derived from similar pustules on the udder of cows. He ascertained the accuracy of a current belief that those who were so affected did not suffer from smallpox. After long investigation he was so satisfied of the fact that in 1798 he inoculated a boy with the matter from a cow's udder (*i. e.* with the cow-pox instead of with smallpox), and finding that this inoculation was as good a protection from the dreaded variola as the other, he made known his discovery.*

The practice of inoculation with this "vaccine lymph" rapidly spread. It was adopted by the best physicians abroad as well as in England, and the process of "vaccination," thus begun, was at last made compulsory in all civilised countries. Vaccination does not absolutely protect from smallpox: inoculation did not, and an attack of smallpox by ordinary contagion does not absolutely protect. But variola, like other exanthems, protects in the vast majority of cases against a second attack; inoculated variola is a mild and comparatively safe form of the disease, and likewise protects from further attacks; vaccination is a still milder and perfectly safe form of disease, and likewise protects from future smallpox.

The statistics given on page 209 show the truth of this assertion. It is also proved by the following example, quoted by Dr Eustace Smith. Dr Gayton had 1574 children under observation in the Smallpox Hospital at Homerton (1871–78). Of these 211 showed good vaccination marks, and only one of them died; 396 showed incomplete vaccination, and 39 of them died; 179 had been vaccinated, but showed no scar, and 46 of them died; while of 788, who unhappily had never been vaccinated at all, no less than 385 died.

* His 'Inquiry into the Causes and Effects of the Variolæ Vaccinæ, a disease discovered in some of the western counties of England, particularly Gloucestershire, and known by the name of the Cow-pox,' was published in 1798.

Similar evidence on a large scale is afforded by the compulsory vaccination carried out in the great Continental armies, by the results in our own army, in the military school at Chelsea, and by observations in Sweden, in Germany, in France, in the United States, and in India.

It is certain that vaccinated persons are to a small extent liable to smallpox, especially if the scars are few and slight, or if the time since vaccination has been very long. Efficient vaccination is necessary to obtain the full benefit of Jenner's discovery. A second vaccination is desirable about the time of puberty, and repeated vaccination is prudently submitted to by those who are going into contact with the disease, as doctors and nurses taking duty at a smallpox hospital.

With delicate persons the local inflammation attending vaccination may be severe, and cause some febrile action and several days' discomfort. With feeble infants the effects may be more serious. And it is now certain that vaccination from a syphilitic child may introduce the virus of syphilis as well as that of vaccinia, especially if blood as well as lymph be inoculated. This is, however, an occurrence so excessively rare that while every precaution is rightly taken against it by choosing healthy infants from whom to take vaccine lymph, the practical risk is infinitesimal.

A much more common but less certainly ascertained drawback to vaccination is that the slight febrile disturbance which attends it may call forth local or general disorders, especially eczema and catarrhal inflammations. Swelling of the axillary lymph-glands of the vaccinated arm and erythematous œdema of the arm itself are frequent, and sometimes, especially in adults, troublesome. Erysipelas or pyæmia is a possible result, but not more frequent than after any other slight puncture.

It has been suggested that these drawbacks, slight as they are, might be avoided by vaccination direct from the udder of a heifer affected with vaccinia instead of from a vaccinated child; and this plan has been extensively carried out. But its disadvantages are greater than its advantages. The operation is less certain of success, the febrile disturbance is usually more marked, and the maturation of the pustule and falling of the scab is considerably delayed. Hence "arm-to-arm" vaccination, from a healthy child to a healthy child, is probably the most efficient, least disturbing, and most practically eligible method.

Course of vaccinia.—When vaccine lymph has been introduced into the lymphatic spaces of the skin, an incubation period of two days follows. On the third a papule appears, which in two days more becomes a vesicle. Towards the end of the first week a large umbilicated vesicle forms, and attains its full development on the eighth day, when a congested halo surrounds it. The lymph then becomes turbid, its contents gradually dry up, the areola fades again, and by the end of the second week a scab has formed. This falls off about the end of the third week, and leaves a pitted depressed scar, at first darker but finally whiter than the surrounding skin. Meanwhile slight pyrexia has begun on the fourth or fifth day, increases at the beginning of the second week, and falls with the maturation of the pustule and the disappearance of the surrounding inflammation.

This process is sometimes slower, as when the vaccinated child is already in the incubation stage of another febrile disorder like measles; and it is sometimes quicker, or otherwise disturbed, as when the child is already affected by some inflammatory affection like eczema.

The course of a second vaccination is almost always rapid, and the

constitutional disturbance usually greater, owing perhaps to the patient's age.

Nature of vaccinia and pathology of vaccination.—Jenner himself believed that cow-pox was modified variola. This was long disputed, but experiments made by Mr Ceeley (1839) and by Mr Badcock (1840) went far to establish the fact. It is therefore supposed that variolous lymph inoculated on a cow's udder produces vaccinia; this inoculated in a human arm reproduces itself and protects from subsequent vaccination, as well as from subsequent smallpox. Yet it is remarkable that the careful experiments more recently carried out at Lyons by Chauveau throw fresh doubt on the question. He found that inoculation of vaccine lymph produces vaccinia in the cow, and that variolous inoculation produces variola. But the latter disease could not be thus propagated, and when both inoculations were made together the variola died out, while the vaccinia could be indefinitely continued. Cows only, not oxen, are subject to vaccinia, because the contagion is conveyed to them from human variola in the process of milking. The disease is only derived by cattle from human beings, and dies out when not thus reinforced. It may also affect horses and probably sheep, though the variola ovina is in certain respects different. The vaccinia of cows is probably the same as one of the diseases known as the "grease" in horses.

If vaccinia is true variola modified by "cultivation," it furnishes the first and hitherto the most successful example of the method of protection from specific diseases by previous inoculation with an "attenuated" virus.

For further details on the subject of vaccination, so interesting as an example of scientific experiment and reasoning applied to medicine, so important in its bearing on general pathology, and so deeply affecting the lives and happiness of the human race, the reader is referred to Dr Seaton's article in Reynolds' 'System,' and his 'Handbook of Vaccination' (1868), to Mr Simon's Reports to the Privy Council relating to the history and practice of vaccination, and to Mr Ernest Hart's excellent popular pamphlet.

VARICELLA*

"Each little pimple had a tear in it
To wail the fault its rising did commit."
DRYDEN.

History of the recognition of Chicken-pox—Its distinction from Smallpox Incubation and onset—Characters of the eruption—Symptoms and course Sequelæ—A disease of children—Diagnosis—Prognosis.

AT the end of the seventeenth century, soon after the final separation measles from smallpox, English writers mention a variety of the lat disease popularly called "chicken-pox." The same affection seems have been described in the sixteenth century by Vidus Vidius, and Ingrassias, under the designation of "Crystalli." Vogel (1764) is said have introduced the name of Varicella. In 1730 Fuller asserted th chicken-pox and smallpox were really distinct diseases; but Heberden, the first volume of the 'Medical Transactions of the College of Physician (1767), first indicated fully the differences between them. He also point out the chief reason which makes the recognition of chicken-pox importa namely, that those who had it might otherwise be deceived into a fa security, which might prevent them from keeping out of the way of t smallpox.

After the introduction of vaccination it became of great consequence distinguish the two diseases, since every case of varicella occurring in vaccinated person would otherwise have been regarded as an instance of t failure of the operation. But it is to be regretted that some of the earli advocates of Jenner's method, being anxious to show that the protecti afforded by it was absolute, referred every suspicious-looking eruption persons who had been vaccinated to chicken-pox. This, in its turn, led a reaction, since it necessarily involved the giving up of all the distincti characters of the affection, and the consequence has been that its claim be regarded as an independent disease has been disputed by several emine physicians, from Dr John Thomson, of Edinburgh (1820), to Hebra, Vienna. Unfortunately, too, the great German dermatologist helped throw the subject into confusion by employing the term varicella in entirely new sense, namely, for all very mild cases of smallpox. It certain that the varicella of other writers is unconnected with smallpox.

The proofs are (1) that it occurs in those who have been vaccinated, who have had variola, just as readily and with the same characters as those who are unprotected; and (2) that a person who has passed through remains as susceptible as before to the vaccine virus or to that of smallpo In the 'Lancet' for 1877 a case is recorded of an unvaccinated child w

* *Synonyms.*—Variola crystallina, spuria, volatica, Variolæ pusillæ (Heberden), Chicken-pox.—*Fr.* Varicelle, *Germ.* Windpocken, Wasserpocken. The word *varicella* evidently intended as a diminutive of variola. The vernacular name is probably a corr tion of *chickpease* (French *chiche*, Latin *cicer*), in allusion to the size of the vesicles.

was admitted into St Thomas's Hospital for chicken-pox, but who was placed on the floor containing the smallpox wards, because the diagnosis was at first uncertain. Two days afterwards vaccination was performed, which succeeded. Eight days later still the child fell ill with modified variola. According to Thomas, Czakert vaccinated with success a boy in whom the inoculation of the cow-pox had failed on three previous occasions, by introducing the lymph into the interior of the vesicles of a varicella with which he happened to be attacked. Indeed, if it were not that at the present day almost everyone is vaccinated in infancy, we should have in the cow-pox virus an almost infallible test, which we could apply at our own discretion, and which would soon clear up all doubts as to the nature of any individual case that might be difficult of diagnosis.

Whereas the fluid from even the mildest eruption of variola is capable of conveying the disorder by inoculation, almost all of those who have tried to inoculate varicella in the same way from its vesicles have failed. Early in the present century Bryce performed this experiment upon children who had never had either smallpox or cow-pox, to the number of thirteen, without any result. It is true that, in a long series of cases collected by Hesse in 1829, there was a small minority in which inoculation appeared to succeed; but according to Thomas there are reasons for thinking that some error crept into these observations.

The characters of the eruption of varicella, and the date at which it develops, are in themselves ample proof of its distinctness.

Incubation.—This seems to be of variable duration, so far as has been ascertained; but it has probably been calculated upon the precarious basis of the interval between the dates at which different children of the same family have been successively attacked. Dr George Gregory stated it at from four to six days; Heberden at eight or nine. Bristowe says that in some cases it lasts exactly a week, but perhaps more commonly a fortnight. According to Thomas, it may be from thirteen to seventeen days; according to Gee, about a fortnight; according to Liveing, variable, about thirteen days with eruption on the fourteenth. Eustace Smith gives seven to fourteen days; Trousseau, from fifteen to seventeen; Dukes, fourteen to nineteen; Eichhorst, thirteen to sixteen.

Onset.—This is usually simultaneous with the appearance of the eruption, so that there is no stage of invasion of the fever before the exanthem appears, as in typhus, enterica, scarlatina, measles, and smallpox.

Thomas took the temperatures of children who afterwards developed varicella (no doubt where the disease was already in the family), and always found them normal or not raised above half a degree (Fahr.), which in childhood is of common occurrence in health.

Even where there are slight prodromal symptoms, as headache or cough, with loss of appetite and feverishness, they only last a few hours before the characteristic rash appears, so that the period of incubation must, as in the case of Rubeola (*sc.* notha) be reckoned up to that of eruption.

In some instances, however, Thomas found that the child was feverish for a few hours before the disease made its appearance, and sometimes the fever lasted two or three days, and was accompanied with delirium or (as in a case which the writer saw some years ago) with convulsions.

The exanthem.—This begins as a series of small, slightly pointed red spots, which Trousseau compares with the rose-rash of enteric fever. Dr Gee says that they disappear when the skin of the part is stretched, this

being a proof that there is no exudation into the tissue of the cutis, but on hyperæmia. In a few hours they pass into as many transparent ten vesicles, round or oval in form, and about as large as split peas. The sometimes have a red base; sometimes they are seated upon a perfect colourless surface, so that the patient looks exactly as if he had been sprinkl with drops of clear water. They are generally scattered quite irregularl but it is said that they may occasionally be somewhat clustered together, as herpes. A chief distinction between them and the vesicles of smallpox is the superficial position: they have no thickened floor, they do not consist of series of separate chambers, and when they are pricked they almost co pletely collapse. Thomas, however, says that when they first appear this not the case, and that they are at that time intersected by delicate sept Most of the vesicles of varicella are rounded, without the central depressi of smallpox; but in almost every case some may be found umbilicated, a occasionally most seem to be so. They appear in crops, which come out succession during the first, second, and third nights of the disorder. At leng they acquire a yellowish appearance, and the fluid in them turns slight opalescent, or may become puriform. After from twelve to twenty-four hou they begin to dry up and become flaccid; they are often ruptured, eith by the nails of the patient (for there is often considerable itching) or some other way; or they fall in first at their centres, so as to acquire spurious umbilicus. Ultimately they form thin brownish-yellow scabs, whi in a few days crumble away and leave reddish pigmented spots.

The eruption of varicella generally appears first on the upper part of t *back* or on the chest, rarely on the face. Formerly it was said to spa the face altogether; and although this is incorrect, it never comes o more thickly there than elsewhere, as is the case with variola. On the sca it is almost always present. Afterwards it spreads to the limbs.

The vesicles come out, not in a single crop, but in a succession of crop which may be prolonged over three or four days or even a whole week. Th one sees papules and vesicles and crusts side by side at the same time; in th it is very different from smallpox. The total number of vesicles is sometim not more than from ten to thirty, but according to Thomas it is general two hundred or two hundred and fifty; as many as eight hundred are sa to have been observed. Only a few come out on the first day—perhaps score. Then a hundred or more fresh ones are seen the following mornin The scabs which form as the vesicles dry up, fall off if left to themselves a week or ten days, and leave reddish marks which gradually disappea but sometimes a few small white cicatrices remain behind; and these m occasionally be depressed, and even pitted.

The *mucous membranes* take part in varicella. Thomas says that co plaints of pain in micturition have often led to his observing vesicles upo the labia of girls, but that on the prepuce in boys they are less commonly be found. On the palate they often persist for some time, having slight reddened bases; but on the lips, the tongue, and the cheeks they are to recognised only in the form of excoriations or small superficial ulcers.

Its varieties.—Some of the papules which, as we have seen, constitu the earliest stage of the eruption of chicken-pox, not infrequently abort a disappear, especially those which come out towards the end of the disea Thomas has recorded a case—the nature of which was established by t fact that the patient's sister had just before had varicella—in which eve single papule died away after thirty-six hours, so that no vesicles were forme

On the other hand, the vesicles sometimes increase in size until they deserve the name of bullæ; such an enlargement of them does not always begin until they have already become scabbed over, and they may go on spreading at the periphery of the crusts for a considerable time. Indeed, it would seem that in exceptional instances varicella lasts much longer than any other exanthem. Trousseau speaks of an epidemic in the Necker Hospital in which, during from fifteen to forty days, blebs like those of pemphigus kept appearing on different parts of the patients' bodies, leaving ulcerations which lasted for six weeks or two months. Mr Hutchinson ('Lect. on Clin. Surgery') saw a rash exactly like fading chicken-pox, which was said to have been out during a month, and which vanished spontaneously afterwards.

Course.—The general *symptoms* of varicella are very slight. In some patients the thermometer fails to rise above normal during the first twenty-four hours, while the vesicles are coming out. In others there is slight fever of two or three days' duration, but it often passes off in a single day. Moderate fever may last four days. It is particularly to be noticed that the temperature in chicken-pox does not fall, as it does in variola, when the eruption begins to develop itself. Trousseau, however, speaks of successive onsets of fever, occurring regularly at night, and accompanying the different crops of vesicles; and Thomas seems to have observed something of the same kind, although he speaks of such exacerbations rather as tending to interrupt the usual nocturnal rise and morning fall of temperature. The maximum temperature is about 102°. In some slight cases there is said to be complete absence of fever throughout the course of the eruption. The defervescence, when it occurs, is usually rapid.

All that need be said about other symptoms is that the patient may be a little restless or drowsy, but that he seldom complains of headache or wishes to be kept in bed. The tongue is clean, but there may be some thirst and loss of appetite. In a child suffering from chronic laryngitis, Dr Gee noticed decided increase of dyspnœa during an attack of varicella.

Sometimes, however, the symptoms are more marked, perhaps more in children above six or seven years old, or in adolescents.

In a case seen by the writer in 1886, the patient, nineteen years old, felt unwell one day, but went out to dinner and was then obliged to leave the table, and fainted. Next morning the rash appeared on her face and shoulders, and continued in successive crops. The highest temperature was 102° F., and it did not rise with the development of the eruption. There were good vaccination marks. The febrile disturbance lasted about three days. One scar only remained on the forehead close to the hair, where a scab had been repeatedly scratched off. There was an epidemic of chicken-pox among children in the village, one of which the writer saw.

Relapses and sequelæ.—Some writers speak of relapses of varicella; and Thomas, although he denies that the disease is ever followed at once by a second complete attack, admits that he has seen a few vesicles appear as late as a month from the commencement of the eruption.

The question bears on a remarkable cutaneous affection which Mr Hutchinson believes to arise out of chicken-pox, and which he therefore terms "varicella-prurigo." He has recorded notes of sixteen cases, all of which are said to have begun with the characters of varicella, most of them having in fact been diagnosed by medical men as examples either of that disease or of modified smallpox. But it is curious that it never affected several children in the same family; indeed, there is only one instance out

of the whole number in which more than one child suffered from the origina disease; and any doubts as to the correctness of Mr Hutchinson's views ar strengthened by the fact that he gives twelve other cases in which the sam skin disease was supposed to have been caused by vaccination. There is n doubt, however, of the validity of Mr Hutchinson's observation of gangren as a complication of varicella, though it is happily a very rare one. In stead of the vesicle running the usual course, it becomes tinged wit blood, and the scab is very large and black. The slight areola is mor marked and of a dusky hue, and under the crust is an ulcer. Thes multiple gangrenous ulcers may prove fatal in young children.

Predisposing causes.—Chicken-pox is almost confined to *children*. D Gee gives a table drawn up from the records of the Great Ormond Stree Hospital, according to which infants under six months of age were ofte attacked, while there was a much larger number of cases among childre between six and twelve months old than during any other period of equa length. Most patients are under six, and after ten years of age it ver rarely occurs. Most writers say that they have never seen it in grown-u patients, but Heberden relates one case in which a mother caught it fro her children, and another instance of it in an adult female was observed b Gregory. Among 584 patients recorded at Basle from 1875 to 1880 b Baader (quoted by Eichhorst), 382 were under five years old and 573 unde ten, 7 were between eleven and fifteen, and only 2 certain cases under twenty

Varicella is sometimes sporadic, sometimes epidemic. Thomas remark that in large towns epidemics are not separated by intervals of several year (as with measles and smallpox), but occur every year or every half-year—i Leipzig regularly a short time after the opening of the infant schools.

This disorder does not affect any particular season, although Heberde speaks of it as occurring chiefly at the end of summer, and Gee thinks it i most common in the fall of the year, in September and October. It is highl infectious. The contagion is probably communicable through the air, and i also capable of adhering to solid bodies. That it possesses comparativel little tenacity may perhaps be inferred from the fact that the extent of a epidemic is not generally large.

Varicella protects efficiently against itself, but not against vaccinia o variola. Second attacks of chicken-pox are almost unknown.

Diagnosis.—The diseases with which varicella has been confounded ar acne, pustular syphilide, and molluscum contagiosum, to distinguish whic needs only knowledge and care—and variola, especially variola in vaccinate persons, and here the distinction is sometimes difficult. The slightness o the early symptoms, the close sequence of the exanthem, the softnes of the papules, their appearance in successive crops, their distribution an rapid course will generally decide the question. If on the second or third day there is a vesicle, or a crust on the fifth, it cannot be variola (Heberden)

The *prognosis* is always good except in the rare cases of subsequen gangrene. There are no other complications and no proper sequelæ; bu occasionally children are some time in regaining strength, and both Gee an Eustace Smith have seen tuberculosis follow chicken-pox.

No *treatment* is needful, except to ease the troublesome itching. The vesicles should as far as possible be protected from scratching, to prevent deep cicatrices. Since the contagion of varicella is very active, isolation i desirable, particularly when young children are in the house.

THE PLAGUE*

"The pestilence that walketh in darkness."

History and geographical distribution—Incubation, onset, and symptoms—Diagnosis—Anatomy—Fatality—Treatment—Conditions of contagion and causes of the decline of the plague.

THE SWEATING SICKNESS.—*History—Symptoms and pathology.*

THE English word Plague was formerly applied indiscriminately to every fatal epidemic disease; and when the malady now to be described appeared in the fourteenth century, it was called the "Black Death." But for the last 200 years the only other epidemics comparable with those of former times have been separately named Typhus, Cholera, Yellow Fever, &c. Consequently we can now use the word "Plague" without ambiguity for what is more precisely termed the "bubonic" or "Oriental Plague."

The history of the true plague, identified by its mortality and its buboes, can be clearly traced back to an Egyptian epidemic under Justinian, about 550 A.D., and notices by medical writers show that it was recognised as early as the time of Trajan. It seems improbable that the "Plague of Athens" described by Thucydides was the Oriental Pestilence.†

Epidemics of the plague were frequent during the Middle Ages, when it was probably almost constantly endemic in Persia, Syria, and Egypt. The Black Death of 1348–49 began in China, spread to the Crimea, and thence by a ship's crew to Genoa, devastated the whole Continent, and put a stop to the war between England and France. Its ravages in Florence were recorded by Bocaccio. It probably reduced the population of England by one third, or even more, and led to important economic results. The same epidemic invaded Syria by way of Armenia, and thence spread over Egypt and the whole of Northern Africa, the hotbed of plague in the days of the Roman empire. There were several epidemics in the fifteenth and sixteenth centuries, and again in 1609, in the first year of Charles I (1625), and in 1635–47; but the most destructive and happily the last in England was the Great Plague of London in 1665, so graphically described by Defoe, although he was but two years old at the time, and could only know what he tells by hearsay. In 1665 no less than 68,596 deaths from the plague were reported in the bills of mortality.

There was a terrible epidemic in the south of France, known as the Plague of Marseilles, in 1720, when the scenes described by the great English novelist were renewed. The disease did not visit Western Europe

* *Synonyms.*—Pestis vel Pestilentia, λοιμός, Pestis inguinaria, Typhus bubonicus, Black death, Levantine or Oriental plague.—*Fr.* la peste, *Germ.* die Pest.

† There is no mention of buboes or of hæmorrhage, and the symptoms recorded are unlike those of the Oriental plague. Murchison believed the plague of Athens to have been typhus, Littré and Daremberg that it was smallpox, and a book has been published to prove that it was scarlatina. It may have been any of these diseases, or relapsing fever, or measles. Except fever and contagion, none of the recorded symptoms fit in with any known malady.

again, but epidemics occurred during the eighteenth century in Sicily and Poland (1743), Wallachia and Russia (1771).

In the early part of this century there were outbreaks of the plague in Malta, at Noja in Southern Italy, upon the Lower Danube, and in the Balkan Peninsula. Up to 1844 they were of frequent occurrence in Egypt, but that country has since been free from them. The disease also vanished from Smyrna and Syria, and hopes were entertained that it had become entirely extinct. But in 1858 it appeared again in Tripoli, on the south shore of the Mediterranean; and it is now known to have visited the highlands of Western Arabia in 1853. There is also reason to believe that it had never been absent for many years together from parts of India; in 1834 an epidemic which occurred in Rajpootana became known as the "Pali plague," and as recently as 1877 it prevailed at Kumaon, on the southern slopes of the Himalayas. Between 1863 and 1876 there were six or seven outbreaks in Western Asia, some in Persian Kurdistan, others upon the Lower Euphrates. In 1877 it showed itself at Resht, to the south-west of the Caspian Sea. From this place it probably made its way to the Lower Volga, where it prevailed, in the district between Astrakhan and Tsaritzin, from October, 1878, to February or March, 1879, and excited great alarm throughout Russia, and in Europe generally.*

This terrible disease, long unknown in Europe, has become rare in the Levant; but it still occurs epidemically at intervals in Yunnan (China), in Kumaon (Northern India), in Irak-Arabi and Syria, in Kurdistan and Northern Persia, in Arabia and in the single town of Benghari, in the province of Barca. It is believed to exist as an endemic disorder in certain parts of Northern India.

The plague does not appear in the tropics, and is stopped by the hot weather in subtropical regions. Nor, with few exceptions, does it survive the cold of winter in European climates. The most favourable temperature is from 60° to 85° Fahr. Dry air above or below these limits seems to destroy the contagion.

It has never extended to the New World, nor to Australia or South Africa, but is not unknown in China.

Course.—The general symptoms of the plague resemble those of typhus. Its *incubation* is believed to be from two to seven, usually from three to five, days. This period is followed by shivering and pains, great malaise, and depression. Intense pyrexia then sets in, the temperature rising to 106° or 107° on the first day; violent delirium is common, and the symptoms rapidly assume a typhoid form. Death not uncommonly occurs at a very early period, before there have been any symptoms characteristic of the malady; it may be preceded by the appearance of petechiæ and large vibices in the skin; there may also be hæmaturia, hæmoptysis, and vomit blackened by altered blood. But if life is prolonged to the second or third day there appear one or more *buboes*, attended with severe pain and tenderness. The seat of this affection may be either the groin (in which case glands belonging to the vertical rather than to the horizontal chain are affected), the armpit, or the neck. According to Liebermeister (in Ziemssen's 'Handbuch') a plague-bubo is sometimes so small as to be detected only on careful examination, but it may attain the size of a hen's egg, or more. Its formation is commonly attended with the subsidence of the delirium and of the fever,

* The English Government sent Surgeon-Major Colville and Dr J. F. Payne to investigate the disease on the spot, but it had already disappeared on their arrival at Astrakhan.

the skin becoming covered with a profuse sweat, and the pulse falling to 90 or 100. It may ultimately subside without discharging; but usually it breaks, or is opened by the surgeon, and gives exit to a mixture of blood and pus, and this may be followed by a tedious process of suppuration, which greatly prolongs the patient's illness.

Carbuncles may be associated with the buboes, but are much less frequent and of more fatal augury. They appear most often upon the lower limbs, on the buttocks, or on the neck; sometimes there are not less than a dozen carbuncles in the same case. Bullæ and pustules may also be seen.

Petechiæ and vibices are usually present over the surface of the body, and constituted the "plague-spots" and "tokens of the plague" in the popular accounts of the pestilence in England. They are more numerous than the petechial spots of typhus, and probably gave rise to the epithet which distinguished the pestilence of the fourteenth century as "the black death."

Pestis minor.—There is a much milder form of this disease, which often precedes or accompanies an epidemic of the plague, and has been called the masked, aborted, or lesser pestilence (*pestis larvalis s. minor, peste fruste*). There is no hæmorrhage in these cases. The buboes are few and chronic, and the pyrexia so moderate that patients usually go about. The illness lasts from a fortnight to a month. Indeed, so slight are some of these cases that they have been regarded as a separate malady; but there seems to be no doubt of their true nature, notwithstanding the absence of cases intermediate in severity. Whether this mild variety propagates itself or not is uncertain.

Diagnosis.—It will readily be understood that to distinguish the plague from other malignant fevers is not always easy, unless the character of a prevailing epidemic has already been determined. Dr Milroy, in Reynolds' 'System,' cites the remark of Heberden that, "on first breaking out, the disease has never been known to be the plague;" and he says that in Constantinople or in Cairo no physician ever ventures to give a name to an epidemic until a case occurs in which a bubo or a carbuncle is seen.* Moreover, as he goes on to point out, similar local affections are sometimes, though very rarely, present in other forms of pernicious fever, whether malarial or contagious. But it is certain that the diagnosis would not have been left open so long as it often has been, were it not for that reluctance to admit unpleasant truths which has always contributed so much to the spread of every infectious disease. According to Dr Milroy, a special difficulty has often arisen, during the prevalence of the plague, from the occurrence of glandular pains and swellings, or of carbuncles, in persons who remain well enough to follow their occupations, and who speedily get well under any simple treatment (pestis minor). Liebermeister remarks that these cases are often observed when an epidemic is declining; the general symptoms are so mild, and run so favourable a course, sometimes without any local lesion appearing, that they may be termed abortive.

Morbid anatomy.—*Post-mortem* examinations throw little or no light upon the pathology of the plague. The viscera are soft and blood-stained, and the spleen is more or less enlarged. The serous membranes are ecchymosed. Some of the internal lymph-glands are enlarged; perhaps a chain of swollen

* In a small treatise, *Pestis descriptio*, by Gratarolus, of Bergamo, published at Paris in 1561, twelve signs of the disease are given, most of which are indicative of any severe fever; but the twelfth is *omnium certissimum: si cum febre post aures aut sub alis aut circa inguina potissimum bubones sine manifesta aliqua causa, aut in aliis etiam partibus carbunculi subito oriantur.* Among the other symptoms *sanguinis sputum* is mentioned.

glands, extending up from the pelvis along the front of the spine, or a mas lying in the mediastinum; their tissue is of a bright red colour, or full o points of suppuration; and blood may be diffused and extravasated into th surrounding structures.* Briefly, the autopsy is one of typhus with th addition of swollen and suppurating lymph-glands.

Prognosis.—The fatality of the plague exceeds that of all other disease It usually destroys from 70 to 90 per cent. of those whom it attacks; ver seldom less than 60 per cent. Moreover, it often carries off half the popu lation of a town or of a district in which it prevails, and it may completel root out whole families, so that no survivor remains. The "Riley Graves, near Eyam, in Derbyshire, still tell of the tragedy that befell two familie in that place during the epidemic of 1666: one, that of the Talbots, con sisting of seven persons, was utterly eradicated within twenty-five days; th other, that of the Hancocks, lost seven out of eight members, the only on left being the mother. It is, however, probable that no small part of th excessive mortality from this disease was due to the fact that, instead o isolating each case at the earliest possible moment, the ancient practice wa to close up every infected house, preventing both ingress and egress, an confining the sick and the healthy together. Those who were attacked wer often left to take their chance of death or recovery. The most favourabl cases have been observed towards the decline of the epidemic.

The contagion.—That the plague is propagated by an infective viru derived from the bodies of the sick is now doubted by no one, although i former times there were "non-contagionists" with regard to this, as to ever other disease. Reasoning from analogy, we should suppose that the *conta gium* is one of the Schizomycetes, but none have yet been discovered in th blood or tissues.

The contagion is persistent as well as active, but it seems to be readil dissipated by the air, and rather to belong to the dwellings than to the bodie of the sick. For many of the clergy and physicians who remained firm to thei duties in the great plague of London escaped, and the same has been notice in more recent epidemics; while, on the other hand, those who live in th same house or room with persons stricken from the plague almost constantl fall victims to the same malady. Moreover, the virus clings to dwelling even after their inhabitants have died or have taken flight. This has led t the belief that the plague belongs to the group of miasmatic contagious dis eases (p. 12); that while the virus always takes its origin from patients, i may persist outside the human body, in the soil or elsewhere. Liebermeister indeed, advocates the opinion that its mode of diffusion is, as a rule, thu "indirect." The statement commonly made that it is inoculable might b supposed to settle the question; but the results of the experiments whic have been made on this point are far from conclusive.

The virus seems often to be conveyed by articles of clothing, wool silk, hair, paper, books, &c. In 1665 the local epidemic at Eyam, i Derbyshire, so well known by the heroism of the vicar, Mr Mompesson, began with the case of a tailor who had just received a box of clothes from London (150 miles off), and who was watching them hanging before the fir when he was taken ill; at that very time the disease in the metropolis wa at its worst. The bedding and the linen of those who have had the plague are particularly apt to be carriers of infection to other persons, sometimes

* The first account of an autopsy is given in a curious work by Dr Geo. Thomson called 'Loimotomia, or the Pest anatomised,' published in 1666.

after a considerable interval of time. When epidemics used to occur in Western Europe, the notion was that it reached Holland direct from Turkey in bales of cotton or silk, and that it was brought over to England from Holland in a similar way. Nevertheless the exportation of cotton from Alexandria to Liverpool and Marseilles during the prevalence of the plague in Egypt in the year 1835 was never prohibited, and yet no cases appeared in England or in France.

Predisposing causes.—Many collateral circumstances, however, greatly influence the spread of the disease. It is said to have been especially apt to prevail where the soil is alluvial and marshy—as, for example, along parts of the Mediterranean coast, and in the basins of great rivers. Warm and damp weather is favourable to it; thus in European Turkey it occurred chiefly in the spring and in the early summer, whereas in Egypt the winter was the chief season for it. In Nubia and in other countries with a hot dry climate it has hitherto been unknown.

Overcrowding, dirt, and poverty seem greatly to encourage its development. It affects especially the poor; and at Malta in 1813 it was noticed, according to Dr Milroy, to be far less common in the upper stories of the lofty houses of Valetta than in the basements. The higher parts of a district sometimes escape when the lower are infected with the plague; thus it is said that the citadel of Cairo and the village of Alem Dag, near Constantinople, used to remain free, although communications with the cities below were not interrupted. Lastly, it seems less apt to occur in persons over fifty years old than in those who are younger, and at least in English epidemics affected more adults than children.

Prophylaxis.—It is greatly to be hoped that the improvement in the hygienic conditions of the inhabitants of Western Europe, which has been going on during the last two centuries, has been the chief reason why the plague no longer appears among us, and that Hirsch is wrong in attributing this result mainly to the system of quarantine. For it is certain that at the present day, if the disease were again to travel towards our shores, there would be extreme difficulty in maintaining that system effectually. Liebermeister cites in detail the proceedings that were adopted to prevent the extension of the plague from Noja in Italy in 1815. The town was surrounded by two deep ditches, a triple military cordon was drawn round it, the soldiers had orders to shoot down anyone who attempted to pass, and no articles were allowed to be sent out except letters which had been first dipped in vinegar. The advantage to be derived from such measures is well illustrated by instances in which large bodies of persons isolated in the middle of an infected city have escaped. Thus Dr Aitken says that during an epidemic at Marseilles a large nunnery was "shut up," with the result that all the inmates remained free, although there was an infirmary on one side for those ill of the disease, and a burying-ground on the other side for those who died of it. This writer, however, speaks of quarantine as a barbarism and as an unwarrantable nuisance; and it is well known that many of the best English authorities hold similar opinions. Indeed, the chief reason why our Government from time to time enforces quarantine regulations, in our possessions in the East and elsewhere, is that if we did not do so, other countries would at once refuse intercourse with our more exposed ports, on the mere chance of our becoming a source of danger to them.

If what has been said above of the persistence of the contagion in houses

is true, we can understand why the Great Fire of London, which destroye most of the City in the year succeeding the Plague, has been followe by complete exemption from the disease. And if the plague is trul miasmatic-contagious, the neglect of cleanliness, and particularly the d filement of the houses and soil which is characteristic of Eastern tow and villages, may be an essential factor in its production.

THE SWEATING SICKNESS.—A few words may be added with referenc to another disease more obsolete than the Plague, which affected Englan in the sixteenth century.

The *sudor anglicus*, as it was called, was an infective febrile epidemic di order characterised by a rapid course, profuse perspiration, and limitatio to this island, or rather to its inhabitants, for it was said to single out ou countrymen wherever they might be abroad.* It first appeared in 148 and was supposed to have been introduced by the motley host which Henr VII led to Bosworth field; for the first recorded cases happened between h landing at Milford Haven, on August 7th, and the battle a fortnight afte wards. On the 28th it broke out in London, and at the same time Oxford, and spread over the whole country with a great mortality. ended as suddenly as it began in December of the same year. The secon epidemic was in 1507, the third in 1517, the fourth in 1528, and th alone spread to Hamburg and thence to all northern and central Europ devastating Scandinavia, Poland, Hungary, and Switzerland, but sparin France, Italy, and Spain, and most of Germany. The fifth and la epidemic was confined to England, Calais, and Flanders. This w described by Dr John Kaye (better known as Caius); it, like previou epidemics, is said not to have invaded Scotland or Ireland.

The onset of the "English sweat" was marked by rigors, headache, a pains in the back and limbs; after a short cold stage like that of ague the followed sudden and profuse diaphoresis with rapid pulse, thirst, and doubt raised temperature. No exanthem is noted, and there is no mentio of sudamina. The course of the malady was remarkably short; fatal cas ended in a few hours with deep sleep and signs of collapse; after twenty-fo hours the danger was nearly past. Relapses, however, sometimes occurre

Various guesses as to the ætiology of this curious disease were mad but it seems pretty certain, first, that it was not due to any of the suppos causes (the English constitution, dirt and squalor, moist seasons, Briti fogs, Continental heat, or too good living), and secondly, that it was (wh Caius denies) an infectious disorder, spreading by human intercourse.

Dr Payne, in an able article on the subject in the last edition of t 'Encycl. Britan.,' argues that this strange epidemic was not really an isolat phenomenon, but closely related to "Miliary fever" (*Schweissfriesel*, *sue miliaire* or Picardy sweat), an epidemic disease of short duration marked fever, sweating and sudamina, not very uncommon in France, Italy, a Germany during the last and the present century; and apparently ende in Northern France. If so, we have a close parallel to the endemic *pe minor* and the epidemic plague, as well as to endemic and epidemic chole and endemic and epidemic measles.

* Dr Payne remarks that this was either because they brought the disease with the or if settled in foreign parts they were merchants in communication with England.

CHOLERA*

"Hæc igitur subito clades nova pestilitasque
Aut in aquas cadit aut . . . . ."
LUCRETIUS.

History—Name—Onset and early symptoms—Stage of collapse—Stage of reaction: the urine at this stage—So-called "cholera-typhoid"—Cholerine—Complications—Post-mortem conditions—Pathology—Ætiology—Theory of contagion—The Comma Bacillus—Propagation of the disease—Diagnosis—Prognosis—Treatment.

IN the winter of 1817–18 there appeared in the camp of the Marquis of Hastings, then engaged in the Mahratta war on the banks of the Sind, a very fatal malady attended with vomiting and purging. Cholera, as it was called, appeared the same year at Jessore in Bengal, and there also was regarded as a new and unheard-of pestilence; but there is reason to believe that it prevailed in India from time to time during the eighteenth century, and indeed as far back as history goes. Mr Macnamara cites numerous notices of cholera epidemics both before and after the appearance of the English in India. During the next few years (to 1823) it spread slowly over a large part of Asia.

The first appearance of Cholera in Europe was in 1830, when it spread from what was apparently its endemic seat in Northern Persia to Russia, and thence to Germany. In October, 1831, it reached Sunderland, and London in the following January. After spreading over the whole of Europe, the new pestilence crossed the Atlantic and was very fatal in the cities of the United States and of Brazil. This epidemic was not over until 1837. Its first outbreak at Paris occurred in the midst of the carnival, and everywhere it came with such suddenness and was so rapidly fatal that it created as much terror as the plague in former times.

The second European epidemic was in 1847–48, when the mortality in London was very great. The well-known surgeon, Aston Key, was one of the victims.

The third, like the others, began in the East and slowly spread to England in 1853. It was one cause of mortality during the Crimean War, particularly in the French and Sardinian armies, and was very destructive in America. In London its effects, though severe, were remarkably confined to certain districts.

The fourth epidemic was in 1865–66. The last important invasion of Europe by Cholera was in Italy and the South of France and Spain (1884–86). At Naples and at Marseilles it was very severe.

Certain regions have hitherto escaped Cholera: Iceland, the Orkneys in Europe, Chili and Peru in the New World, the Cape Colony in Africa, and the whole of the Australian continent.

* *Synonyms.*—Epidemic, Asiatic or Indian, malignant or blue cholera; Cholera pestifera, Cholera morbus, Cholerica passio. In India the word *morxi*, used by the Portuguese in the sixteenth century, probably denoted cholera. The French in the Deccan called it "*mort de chien.*"

Name.—The term "cholera" does not seem to occur in the Hippocra writings, but it is used by Aretæus and by Alexander of Tralles. T description by the former writer (De causis et signis acutorum morbor lib. ii, cap. v) refers to severe diarrhœa with vomiting; the evacuations said to be first fæcal, then mucous (φλεγματώδεα, pituitosa), and las bilious (χολώδεα); pains, cramps, scanty urine, feeble and frequent pu are given as the symptoms which accompany this disease; none of th characteristic of Asiatic Cholera, as distinct from severe diarrhœa.

The word χολέρα is usually and probably rightly derived from χο and means bilious diarrhœa. So Celsus understood it: *bilis supra infra erumpit, primum aquæ similis, deinde ut in ea recens caro lota esse videat interdum alba, nonnunquam nigra vel varia. Ergo eo nomine morbum h* χολέραν *Græci nominarunt* (lib. iv, cap. xi).*

The name applied to the new disease was extremely inappropriate, Indian cholera is marked by an absence of bile in the matters vomi or discharged from the bowels. For a time the epithet "Asiatic," applied to the new malady by way of distinction from so-called "Engl Cholera." But of late it has become usual to speak of the epidemic order alone as *cholera*, and to classify as diarrhœa or gastro-intestinal cata sporadic cases which are now and then seen, although their symptoms more or less "choleraic" in character.

Course.—After exposure to the exciting cause of the disease, there i short period of *incubation*, which is believed to be generally two or th days, but sometimes not more than twelve or twenty-four hours. Goodeve cites an instance, recorded by Dr Barry, in which a detachment sepoys, on their march from one place free from cholera to another, pas through a village where it was raging; one of the sepoys was attacked a forty hours, and fresh cases appeared subsequently.

The invasion of cholera may be either gradual or sudden.

When the disease sets in gradually, the earliest symptom is genera diarrhœa, which is often called "premonitory," attended with gripi pain and with a sense of exhaustion. In some cases malaise, depress of spirits, headache, vertigo, noises in the ears, oppression at the epig trium, are present during this period. At the London Hospital in 186 nurse was doing her work as usual when she was attacked with "singing her ears," and nausea; so that she lay down hoping that her sympto would pass off, but they were quickly succeeded by those of chole Another patient there complained not only of noise in the head, but being pained by the sound of his own voice; and a third kept shifting head from the top to the bottom of his bed every few minutes, trying escape from the ever-pursuing noise. The countenance of a patient duri the premonitory stage is often pallid, anxious, and sorrowful. Annesl cites a case in which the approach of cholera was suspected mainly fr the aspect of the patient nine hours before the characteristic sympto appeared. The duration of the premonitory symptoms varies from a f hours to two or three days.

In many instances this stage is altogether absent, and then the dise

* Alexander Trallianus gives another etymology: *Intestina vero* χολάδες *veteres app labant ut etiam Homerus testatur. . . . Hujus gratia etiam affectum* χολέραν *nuncupar* (lib. vii, cap. xvii). Hesychius's Lexicon (quoted by Liddell and Scott) gives a seco explanation of the word as an application of χολέρα, "the gutter of a roof down wh the rain is discharged:" but this is nonsense.

with startling suddenness. It very often—according to than half the cases—begins in the early morning, perhaps nt up from sleep.

nptom of the developed disease is violent *purging;* the con- els are rapidly swept out in a fluid form, and the discharges ost colourless, like whey, or like water in which rice has at they are commonly spoken of as "rice-water stools." On id deposits a loose whitish-grey material, which consists of containing numerous leucocytes, and immense numbers of ng various bacteria. At one time it was thought that ial cells were present, but this is now known not to be the er fluid discharges during life, although what is found after death is full of them. The specific gravity of the 006 to 1013; it has a neutral or slightly alkaline reaction, ains chloride of sodium, with a very small quantity of ofuse is the flow that Dr Goodeve speaks of the patient as pan of a night-stool in two or three hours, and sometimes pints or even quarts. He remarks that when all that is d in the same vessel, the bile contained in what was first it a yellowish colour. Sometimes the tint is pinkish from f blood. There is often no pain whatever in the bowels, s complain of more or less griping.

erval, or occasionally at the very commencement of the ets in; the fluid rejected from the stomach (unless mixed pale and watery, being in fact identical with the rice-water even have a still lower specific gravity of 1002 to 1005, a large admixture of water taken in during the attack. It ut of the mouth suddenly and with great force.

y symptom is severe *cramp* in the muscles of the feet, in the s, and sometimes in the thighs, hands, chest, or abdomen. es on at intervals and lasts for a few minutes at a time. It nising character, causing the patient to shriek out and to e bed on which he is lying. Lebert says that cramps were a third of the cases observed in the epidemic at Zürich

collapse.—These symptoms are followed by the develop- kable condition, known as "cholera collapse," the "algide nonly appears within six or seven hours of the commence- ging, and often earlier still. Indeed, in some exceptional actually dies collapsed before there has been either vomiting the rice-water fluid is found accumulated in the bowels after ential sign of this state is a failure of the circulation, begin- iphery, but afterwards affecting parts less distant from the e at the wrist becomes more and more feeble and thread-like, ther imperceptible; even the brachial artery may no longer on auscultation, according to Lebert, the second sound of e inaudible, while the first sound is still heard. The surface mes cold, livid, and shrunken. The hands feel like ice, and s though they had been long soaked in water. The features ue, the eyeballs are deeply buried in their sockets, the nose ongue feels cold, even the breath may be entirely devoid of kin is often covered with a profuse sweat.

According to Goodeve a thermometer placed in the mouth indicates fr 79° to 88°. In the axilla, however, the temperature is seldom below 93° 94°, as was shown by careful observations made at the London Hospital 1866 by Mr F. M. Mackenzie. And in the rectum, or in the vagina, t temperature rises through the period of collapse, reaching 100°, or 102°, even 104·4°. Mr Simon, in discussing these facts in his 'Ninth Repo infers that the choleraic affection of the bowels is a "heat-making" proce But there seems to be no reason for doubting that the heat is generated the muscles and in the glandular organs, just as it is under ordinary c cumstances. Mr Mackenzie observed that a severe attack of cramp rai the axillary temperature as much as 2° F. The only question seems to whether the elevated temperature in the interior of the body is due to mere accumulation of heat from deficient loss, or whether there is positive shifting upwards of the point to which heat regulation is set, in true pyrexia. It is a strong argument against the latter view th during reaction, as we shall presently see, when the peripheral circulati becomes restored, the internal temperature falls and is actually below norm Moreover, the collapse of cholera is essentially different from the init rigors of acute specific diseases. One distinction on which Hutchinson l insisted ('Lond. Hosp. Rep.,' vol. iii), is that in collapse the pupils are natural size, whereas in rigor they are widely dilated.

The breathing during collapse is increased in frequency, being at t rate of 24, 30, or even 40 in the minute; and there is often a sensation dyspnœa. The heart's action, however, is but little accelerated, remaini at about 100. There is great muscular weakness. The voice becon feeble and whispering, or may be so completely extinguished that when attempt is made to speak nothing but a movement of the lips follo Lebert thinks that this is due to dryness of the vocal cords, as well as relaxation of their muscles. In some cases the patient has been known sit up, or even walk across the room, very shortly before his death, but a rule, he becomes unable to rise from the recumbent position. There usually great restlessness, the limbs being abruptly tossed and jerked abo

The mental state is generally, from the first, one of indifference rath than of anxiety; and in some cases it is only when the cramps cause t sufferer to cry out that he seems to be conscious of his condition. But can easily be roused to understand what is said to him, and may answ quite rationally. Coma sets in only towards the very last, if at all.

It is to be noted that when collapse has developed itself in a mark form, the purging ceases altogether, or becomes greatly diminished. Probab what is now passed had been poured out into the bowel at an earlier perio Goodeve describes it as often containing gelatinous mucus-like masses. T stomach, however, still remains very irritable. There is the most inten thirst; the patient craves for water, and drinks it with eagerness, only vomit immediately afterwards. Another distressing symptom is a sense burning heat at the epigastrium, often accompanied by great tenderne and sometimes by hiccup. The abdomen is commonly retracted.

Lastly, one of the most marked phenomena of collapse is *suppression urine*, which seems often to be present from the earliest period of the d ease. There is no doubt that the arrest of the renal secretion in cholera a result of the defective flow of blood through the kidneys. Herma and Cohnheim have independently shown that precisely the same thi occurs in animals when the renal arteries are compressed or ligatured.

—Cholera collapse often leads directly to a fatal termination, akes place between twelve and twenty-four hours after the of the attack, but sometimes earlier, and sometimes during

tions that before death the eyes may become dry and the opaque. The internal temperature has often been found has become extinct; and spasmodic twitchings and quiverings have sometimes been observed within the first half-hour ne limbs may actually move; in a case at the London Hospital ow became raised about three inches above the level of the ich it was lying.

Not infrequently, even extreme collapse is recovered from. *ction* usually begins to develop itself at the end of twenty-ht hours. Goodeve remarks that the subsidence of restless-tion is often a favourable sign. The patient dozes quietly ation; then a flickering pulse at the wrist is detected, which es more distinct, the superficial veins on the back of the fill, the surface is felt to be less cold, the features look less colour begins to return. As a rule, the improvement occurs by step. But the older Indian physicians spoke of cases " standing at his door on Wednesday, was in perfect collapse

o Mr F. M. Mackenzie the temperature during reaction, when fairly recovered, is usually about 97° in the rectum or the ° in the axilla ('London Hosp. Reports,' vol. iii). But in he London Hospital in 1866 it was observed that certain face conveyed to the hand a sensation of burning pungent e of which, however, was not determined by the thermo-r point noticed at the same time was that the pulse often even to 45, in patients who were doing perfectly well. other hand, speaks of the pulse as remaining at about 100. es full and bounding, and may be dicrotic. The patient's ar. The cheeks usually present sharply defined patches of the conjunctivæ are deeply injected, the eyes half closed turned upwards, the expression heavy and vacant.

of reaction is by no means free from danger. Sometimes a purging, vomiting, and exhaustion set in again, and end er cases the reaction is said to be *imperfect*. The pulse up to a certain point, remains weak, and the surface of the to be colder than natural. The bowels are still relaxed ions are watery, although more or less coloured with bile. etite and the patient is depressed and drowsy. Sometimes nent symptom is irritability of stomach attended with thirst nsations along the œsophagus and at the epigastrium. entions sleeplessness, lasting for two or three days or more, t discomfort to the patient.

anthem.—In some cases slight pyrexia occurs at this stage, d with the development of a bright crimson or scarlet *rash*, nly spoken of as a roseola, though it may rather have the rticaria. Sometimes it nearly resembles the eruption of Mackenzie found in 1866 that it was always accompanied perature, both external and internal. In one instance the

former was 101·6°; the latter 102·4°. The backs of the hands and the forearms are its favourite seats, but it may also cover the trunk, and even be seen on the face. In the museum of Guy's Hospital we have excellent models of this choleraic roseola made during the epidemic of 1854. It seldom comes out until a week or ten days after the commencement of the attack, and in one case recorded by Wilks it did not appear until the seventeenth day. It lasts two or three days, and may be followed by desquamation. It is more often observed in young patients than in old, and is particularly well marked in children. As a rule, the cases in which it occurs end in recovery.

Urine.—In the reaction of cholera the most important condition is that of the kidneys. We have seen that during collapse there is generally complete suppression of urine; if any is secreted it is apt to be, even at that period, albuminous. When reaction sets in, the suppression often continues for several hours, or even for two, three, or four days. According to Buhl, if it lasts up to the sixth day the case is hopeless. Sometimes, however, when the renal function has been re-established, the patient fails to void the urine in the bladder. The hypogastric region must therefore always be carefully examined, and, if necessary, a catheter must be passed. The instrument should be new and lubricated with carbolic oil, for cystitis and pyelitis have often been observed in cases fatal at an advanced stage. In a woman who died in Guy's Hospital during the epidemic of 1866 there was suppurative nephritis, which appeared to have arisen by extension from the bladder.

The urine which is first secreted during the reaction stage of cholera is described by Goodeve as high coloured, acid, and possessed of a strong animal smell. As to its specific gravity there are some discrepancies in the recorded observations. At the London Hospital in 1866 it was found to range from 1005 to 1017, the average being 1006. Wyss, however ('Arch. d. Heilk.,' 1868), found that the density of the first urine passed was from 1012 to 1033, the average being 1020. It was only at a later period, when the quantity was more abundant, that it fell to 1010, or even lower. The amount of urea and salts is much diminished, but albumen is generally present, and sometimes blood, and there are usually hyaline casts in immense numbers. Lebert says that the occurrence of albuminuria at this stage is constant, but his statement does not accord with the experience of English observers. At the London Hospital in 1866 albumen was found "in about half the cases examined." As a rule, the urine continues to be coagulable during from two to seven days. Until recently the renal affection attended with albuminuria in cholera was commonly regarded as parenchymatous nephritis, and as comparable with the acute renal affection that follows scarlet fever or diphtheria. But Bartels, in 'Ziemssen's Handbuch,' regards it as the result of the ischæmia which exists during the stage of collapse, and this view has since been upheld by Cohnheim.

In cases fatal before reaction has set in, the kidneys are found small, tough, and of a dark brown or slightly livid colour. At a later stage they are much enlarged—Dr Moxon speaks of them as weighing up to fifteen or sixteen ounces—soft, greyish white, or yellowish. The epithelium very early becomes cloudy, opaque, or fatty; it has lately been suggested that this change in it is analogous to the "coagulation-necrosis" which Litten has found to occur in the renal epithelium of rabbits after arrest of the arterial blood-current through the kidneys. The Malpighian tufts and their capsules

rerichs, most writers regard this complication of cholera as
Urea has, in fact, been found in the blood in cases of
by several observers. Buhl estimated the quantity of it in
2 per cent. In some instances, too, there has been observed
l neck an efflorescence of urea in a crystalline form, excreted
nds. But Goodeve has observed that in some cases a con-
ttended with typhoid symptoms, occurs independently of
least while urine free from albumen is being secreted.
Vagner drew attention to the same fact, and attributed the
inflammation of the intestines or other internal organs.

.—There are certain minor forms of cholera, cases of which
uncommon, but of which the frequency in relation to that
isease cannot be positively stated, because they are often
eir course without being brought under medical observation.
ommonly called "choleraic diarrhœa." It is identical with
y diarrhœa" already described, except that it subsides after
not pass on into cholera. It often begins suddenly, after a
patient has eaten unwholesome food. There are three or
cuations of yellow fæcal matter daily, with some pain, and
ght cramps. A more severe form is sometimes termed by
s "cholerine;" it is attended with vomiting, with cramps,
disappearance of bile from the stools, and even with some
ss of the limbs. Lebert says that he has seen it followed
yphoid symptoms.

and sequelæ.—The convalescence from cholera may be
certain complications, which require brief mention. One of
ion of the lower segment of the cornea, generally of each
less results from the part having been exposed and irritated
of collapse. It now, four or five days after reaction,
covered with a layer of opaque lymph; and ulceration
in it. Sometimes perforation takes place, but generally—
uld recover, which seldom happens—the eye is preserved.

In other cases, during the second or the third week the parotid gland swell or suppurate. This interferes with swallowing food, often with fatal result. Sometimes bronchitis, pneumonia, or pleurisy sets in; o diphtheritic inflammation of the fauces, or the bladder, or of the sexu organs, or gangrene of the scrotum or penis, or even of the nose. Bedsore too, are often a source of danger at this period of the disease.

Morbid anatomy.—This throws but little light on the pathology of choler The bowels commonly contain more or less of the rice-water fluid; thi microscopically is found to contain an immense quantity of columnar epith lium, not only loose cells, but coherent masses of considerable size, formin complete casts of the villi. If there is no liquid, the cast-off epitheliu forms a soft creamy pulp. At one time the opinion was held that sheddin of the intestinal epithelium was the fundamental lesion of cholera; but it now known to be of *post-mortem* occurrence. For not only are the cel absent from the evacuations passed during life, but (as Cohnheim observe denudation of the mucous membrane, if it took place before death, could n but be followed by severe inflammatory changes. All that is found is slightly injected, swollen, and œdematous condition of the intestinal coa with perhaps some ecchymosis of the valvulæ conniventes. The lymp follicles in the mucous membrane are also in many cases enlarged, a Lebert says that there may be slight ulceration of Peyer's glands. In case that occurred in Guy's Hospital in 1854 the lining of the rectum show a patch which was œdematous and sloughing, with suppuration in the su mucous tissue. The peritoneal coat may be reddened and sticky, and 1866 Dr Moxon found in one case, in which the collapse had been unusual protracted, that a tenacious viscid material like spider's web lay between t coils of intestine, and could be drawn out into long filaments by separati one coil from another. Other points on which he insists are the want fæcal odour and of the blackening produced by sulphuretted hydrogen, a the absence of gas in the intestine, so that the coils lie in a flabby compact ma in front of the spine. The mesenteric glands are sometimes slightly swolle

The blood which is found in the heart and in the great vessels is remarkab viscid and tarry; and whenever venæsection has been practised during lif the same peculiarities have been seen. This state of the blood, however, is n peculiar to cholera; for it was well marked in a patient who died in Guy's Ho pital in 1871 of acute ulceration of the intestine. It is no doubt a consequen of the drain of fluid from the body. Another result, which has been not by more than one observer, is the disappearance of dropsical effusion in t course of a few hours when the patient happens to be attacked by cholera.

In all probability the change in the blood is the cause of the formati during life of ecchymoses, which at the autopsy are often found scatter over the outer surface of the heart, upon the pulmonary pleura, in the p mater, and elsewhere. All the tissues are peculiarly dry. Cohnheim r marks that the serous cavities in the dead body of a cholera patient have soapy feel, which is not likely to be forgotten by anyone who has ev put his hand in them; and the spleen, the lungs, the liver, and the oth organs are tough and leathery. The peculiarly shrunken appearance of t lungs is attributed by Dr Moxon, no doubt correctly, to the dry, empty sta of the bronchi, which allows the elasticity of the organs to drive the air o of them more completely than usual after the chest is opened. On t other hand, when death has occurred during reaction, the smaller tubes a

f pus, and parts of the lungs may be œdematous, or even cho-pneumonia.

ne whole course and natural history of an epidemic of into close relation with the specific contagious fevers of hus, smallpox, and scarlet fever are types; and we shall see s now ascertained to be infectious, though not in the direct which is observed in those maladies; its mode of spreading of enteric fever, and it may be not improperly regarded alady as a "miasmatic-contagious" disease (p. 13). More- han probable that the *contagium vivum* has already been form of a vibrio, to be presently described.

ia, which we have hitherto found to be a constant attendant of a swarm of microphytes, is either absent or strangely it appears in a slight, inconstant, and equivocal form. ng prevents this virus from reaching the thermotaxic ous system; or possibly some thermolytic process prevents g the temperature from being manifest. Or it may be that nicrobes is chiefly or entirely local, and that the intestinal lf the cause of the thickened blood, the low temperature, nptoms.

nsider cholera as a local inflammation, like erysipelas or from the absence of pyrexia, the characters of the rice-water ke those of any known inflammatory exudation, in any part we cannot possibly suppose it to be of that nature. An ever, originally made by Moreau, suggested the clue to ce. Physiologists had previously learnt from Thiry how to of the intestine, so as to obtain from it an unmixed in small quantity. Next Moreau found that when an ntestine has all the nerves in its mesentery cut through, it thin a few hours at latest, with an abundant secretion of a owish fluid, which is of very low specific gravity, which s mucous flocculi, but in which there is only a very small nen, while the chief salts in it are those of soda.* There ytic over-secretion of the succus entericus and, according sesses the property of converting starch into sugar. But at the rice-water liquid of cholera likewise contains a fer- property, beside corresponding closely with succus ente- respects. The inference, therefore, seems justifiable that holera is nothing else than the secretion of the intestinal ly increased in amount. Whether its formation should be n of paralysis of the splanchnic nerves is left by Cohnheim

In proof that the muscular coats of the bowel are not in cholera he cites the fact that *post-mortem* invaginations which occurred after or shortly before death. But he in- alled "cholera sicca," in which rice-water liquid is found in er death, though none had been voided during life, owes its n early exhaustion of the excitability of the intestinal walls;

ts have since been confirmed and extended. See the Reports of the l by the British Association, published in the 'Transactions' for 1874 o papers by Dr M. Hay in the 'Journal of Anatomy and Physiology' vol. xvii, p. 441), and by Dr Brunton and the present writer in the November, 1884, *et seq.*

and he refers to the same cause the frequent cessation of vomiting a purging as collapse becomes developed.

The above view with regard to the nature of the rice-water liqu strongly supports the doctrine held on other grounds by many observe that the primary action of the cholera virus is upon the solar plexus rath than upon the bowel itself. Cohnheim, indeed, agrees with those who thi that the phenomena of collapse are adequately explained by ascribing the to the drain of fluid from the body, and to the viscid inspissated conditi of the blood which we have seen to result from it. This opinion was oppos several years ago by Dr George Johnson, one of whose arguments was th no relation could be traced between the degree of severity of the collapse in given case and the amount of fluid discharged from the stomach and fro the intestine. A stronger argument has since been advanced by M Sedgwick, namely, that cholera collapse closely resembles that which follo cases of perforation of the stomach, of intestinal obstruction, and of oth abdominal diseases in which no purging occurs. At Guy's Hospital, duri one of the London epidemics, a man actually died of internal strangulati of the bowel who was supposed during life to be suffering from the so-call "cholera sicca." It must therefore be supposed that collapse is the result some disturbance of the abdominal sympathetic. This disturbance, ho ever, is by no means identical with that which causes syncope. Chole patients have no sensation of faintness; and even when they have no pul at the wrist they may be able to sit up or to walk about without sudde failure of the heart's action. On the other hand, the collapse of cholera essentially different from rigor. The suppression of urine which occu in collapse is a part of the general state, since it is observed likewi in cases of acute intestinal obstruction, of perforating ulcer of the stomac and of arsenical poisoning. Thus few pathologists agree with Dr Johns in endeavouring to trace all the phenomena of cholera collapse to obstru tion of the flow of blood through the pulmonary capillaries. An although the high authority of Parkes can be cited in proof of the fa that the lungs weigh much less than usual in cases of cholera, this may b sufficiently accounted for by the diminished volume of the blood generall since the lungs contain so little solid material that their weight, so long a they retain their spongy character, must be mainly that of the fluid in the vessels or in their interstices. During the epidemic of 1866 we entirel failed to observe that the branches of the pulmonary artery and the righ side of the heart were distended or gorged with blood when death ha occurred even at an early stage. It is true that cholera is attended with lividity which is wanting when collapse is due to other causes. But th altered constitution of the blood may be fairly supposed to interfere with it due aëration, and the amount of carbonic acid exhaled from the lungs ha been shown to be much reduced.

Absorption is retarded, although not entirely annulled. Magendie i said to have found that when camphor was injected into the rectum, fiv minutes elapsed before its odour could be detected in the breath, instead o only one minute, as in health; and Lebert states that atropine fails t dilate the pupils when administered by the mouth, though not when injecte into the blood. It is, however, a very curious circumstance that in women who are suckling children the secretion of milk continues during collapse even to an extent which is troublesome. The menstrual flow also goes on unchecked; it may actually set in, before reaction is established, if the prope

ound for its appearance. A sanguineous muco-purulent he vagina also frequently appears, independently of the n the disease seizes upon a pregnant woman, the fœtus die; if the period of gestation is early, abortion takes e mother often dies undelivered. those who nurse or visit him. A few instances have indeed been record which look as though direct infection did sometimes occur. Thus, in paper in the 'Edinburgh Medical Journal' for 1838, the late Sir Jam Simpson related how certain mendicants brought cholera with them Bathgate on May 27th, 1832, and how one of the nurses who attend upon them was attacked and died on the 30th. He also cites the case of woman who, having caught the disease at some ironworks where it rag and being afraid of being sent to the hospital, went on May 12th to a cotta where her mother lived, four or five miles off: on the 14th the mother f ill, and died in a few hours. Dr John Snow relates that a man who had be working at Chelsea died at Streatham of a bowel complaint which last only a day or two: at that time no other deaths from cholera had be registered within two or three miles of Streatham, but the man's moth who attended him, was taken ill on the very next day and quickly s cumbed to the disease. But instances of this kind are very rare, and, a rule, persons who come into contact with patients are scarcely, if at a more likely than others to fall victims to cholera.

The explanation is believed to be that the contagion of cholera escap from the body in the rice-water evacuations, but that it is not then in active state, and becomes so only after an interval of from two to four five days; in other words, the evacuations are supposed to be infective on at a certain stage in their decomposition, and not when they are fres The evidence in support of this view consists mainly of the results of exp riments made by Thiersch in 1854, and repeated by Burdon Sanderson 1866. These observers took liquids passed by patients during life, or tak from the intestines after death, and left them exposed to the air in gl vessels. Every day pieces of filter-paper were carefully soaked, one wi each liquid, and dried. The paper was then given to mice, a square in to every animal. The consequence was that a considerable number of t mice died with an extremely low temperature and with disturbance of t functions of the intestinal canal, their excrement being soft and altered colour. Of the mice employed by Sanderson, 11 per cent. suffered wh the rice-water liquid had been one day old, 36 per cent. when it had be two days old, 100 per cent. when three days old, 71 per cent. when fo days old, and 40 per cent. when five days old; by the sixth day it becam innocuous again. The morbid appearances found in the mice after dea appeared to be consistent with the view that they were affected with chole and Mr Simon afterwards expressed the opinion that the value of th experiments in explanation of the facts of human infection was conclusiv No equally satisfactory results have hitherto been obtained with other kin of animals; but some instances have been recorded of dogs being attacke by a fatal disease resembling cholera after having devoured matters vomit by cholera patients, and in 1853 Dr Lindsay set up a similar disorder dogs by confining them in a small room, the floor of which was strewed wit the excreta of such patients.

It may be thought that if a living organism, possessing specific properties is present in however immature a form in rice-water discharges, it ough to have been long ago discovered. But the alvine evacuations, even i health, contain various microphytes in large numbers, and it is therefore b no means surprising that the search for special cholera microzymes was lon unsuccessful.* Dr William Budd, indeed, published figures of what he sup

cholera fungus as far back as 1849; and many observers similar discoveries, but their statements all lacked evidence.

bacillus.—When the epidemic of cholera which prevailed in in 1884–85 first made its appearance in Egypt, the German t thither Dr Robert Koch, who had lately discovered the rcle. As the result of his examination of the disease at believed that he had ascertained its contagium vivum to be aped organism, which he called a bacillus. He was after- ombay, where cholera was prevalent, and there announced hyte characteristic of cholera was of a curved shape, and this character "the comma bacillus of cholera"—an un- for it is in form not a bacillus but a vibrio. Subsequent only confirmed Professor Koch in this belief, which is competent observers.

ever, opposed to the opinions of the majority of Indian t with much adverse criticism. The late Dr Timothy Lewis, f the *Filaria sanguinis*, stated that the so-called bacillus is met with in the mouth of healthy persons, and it was ases of diarrhœa by Prior and Finkler in Germany. The ment sent Dr Klein and Dr Heneage Gibbs to India to subject, and their report was adverse to Dr Koch's theory. yal Society and Medical Research Association united to send mbridge, to investigate cholera then prevalent in Spain, and year the same Association deputed Dr Sherrington (who l Dr Roy in Spain) to clear up doubtful points by researches holera was still partially epidemic in the summer of 1886. l also been made by French physicians at Toulon.

t of these difficult and prolonged investigations it must be Koch's conclusions were premature. This was the verdict n Sanderson and also by a Commission appointed by the ne and report on the evidence.*

the criteria for determining the causal relation of a micro- ntagious disease stated on p. 13, we ask the following *Is the disease itself definite and capable of accurate diagnosis?* the marked and striking character of the symptoms and a given in the preceding pages, there is no doubt that slight ur during an epidemic might at other times be put down as rrhœa; that the diagnosis between so-called cholerine or cholera (both of them bad names), and true Asiatic malignant difficult or perhaps impossible; and that isolated cases occur ch, in the judgment of cautious and experienced men, are from genuine cholera and yet do not spread the disease. *ortem* appearances are not always uniform or decisive. Dr nd that a large number of the supposed cases of cholera in y diarrhœa, or enteric fever, and Dr Roy had observed the Even granting, what is no doubt true, that if sufficient care ecting well-marked cases, no appreciable risk of mistaken

ng either to *Cercomonas* or to *Trichomonas*, are found in excreta of om cholera in unusual numbers and in a peculiarly active state, but he r to some extent under other conditions of disease, and even in health. bæ to be very abundant in certain cases of cholera; bacteria, he says, e part even of the normal fæces, at least in India.

given in full in the 'Quart. Journ. of Micr. Sci.,' vol. xxvi, p. 303.

diagnosis is present in the case of men, the difficulty becomes very mu greater when we seek to determine whether the clinical features or t morbid anatomy observed in mice and other animals entitle us to regard disease induced in them to be the true cholera of man.

(2) *Is the microphyte clearly distinguishable from others?* This we m probably allow as the result of many patient and independent investigatio The organism is not properly called a bacillus, it is a vibrio, or rather fragment of a vibrio, and it is indistinguishable in size, shape, or reaction staining agents from Lewis's microphyte. But when cultivated its coloni show distinctive characters, so that mistakes may be avoided by adequa experience and pains.

(3) *Does the microphyte only occur in cases of cholera?* The answer this question in involved in the preceding. Very similar or morphological identical comma bacteria occur in the alimentary canal both in health a disease, but the genuine organism, tested by its growth and development well as its form and size, has not yet been proved to exist except in t intestines or the dejecta of cholera patients.

(4) *Is its occurrence in cases of the disease constant?* This is not y proved, but in the great majority of cases there are numerous "comm bacilli" to be found in the intestinal contents, and occasionally their abun ance approaches what Koch called a "pure cultivation" in the small inte tines. But they do not occur as the spirillum of Relapsing Fever, and (as w shall afterwards see) the bacillus of Anthrax, in the blood or tissues. T commas are found in the dejecta and in the rice-water contents of t bowels, and also in the detached epithelium found after death loose in t ileum, but they have never been discovered deeper than the epithelium, at furthest the *mucosa* (corium), of the intestinal walls.

(5) *When separated by cultivation from other organisms, does a new bro of the microphyte reproduce the original disease when introduced into the circul tion of an animal?* This, the last and crucial proof of the causal relati of the plants to the disease, is wanting in the case of cholera. Koch's i oculations are far from convincing, and the attempts of others to reprodu cholera by introduction of the commas into the stomach or intestine blood of various animals have not succeeded, even when the acid digesti of the stomach has been evaded, or when the influence of the bile has be excluded by ligature of the bile-duct. Whether man is the only anim capable of contracting cholera, whether the right animal has not been fou (for the earlier experiments of Thiersch and Sanderson above-mentione are inconclusive), or whether the contagium of cholera is another microphy than the comma—these are questions not yet decided, but at present t evidence that the true contagium has been discovered is defective.*

Nevertheless, the comma vibrio is so constantly present in cases Asiatic cholera that, as Dr Klein admits, its discovery in the fæces duri life or in the intestines after death is a proof of the nature of the disease.

Modes of transference of the contagium.—Passing on now to consider how t contagious principle of cholera gains access to the human body, we find t best ascertained fact to be its frequent entrance by means of drinking-wate

* Klein observed some very minute rod-shaped bacteria to be more constant in the int tines than the comma vibrios, and thinks they may be more closely related to the disea Emmerich found straight bacilli in the blood of cholera cases.

It may be that bacteria in the intestines cause diarrhœa with catarrh of the muco and that in this nidus the true contagium of cholera finds its suitable conditions for d velopment.

hn Snow deserves special commemoration, not only as having
o uphold this view with regard to the ætiology of the disease,
aving devoted infinite labour and pains to establish it. He
nces occurring as far back as 1849, in which local outbreaks
ore or less conclusively to the contamination of surface-wells
e such occurred in Thomas Street, Horslydown, another in
, Wandsworth, a third at Salford, a fourth at Ilford. The fol-
was very striking. A gentleman who lived at Bath was the
houses at Locksbrook, near that town. Cholera, which did not
, appeared at Locksbrook and became very fatal. The people
the water of the well attached to their houses, drainage
ools having entered it. The owner went to the place, said he
thing wrong with the water, was asked to taste it, and drank
This was on a Wednesday; he returned home, was taken ill
nd died on the Saturday.

not until 1854 that the evidence of the communication of
king-water became irrefragable. Then occurred the celebrated
d around Broad Street, Golden Square, which is said to have
n days more than five hundred persons living within a radius
This was traced by Dr Snow to the water of a surface-well,
tuated at the corner between Cambridge Street and Broad
t sixty-eight of the first eighty-three deaths occurred in persons
lly known to have drunk the water in question; and it may
at many took it without being aware that they did so, mixed
ublic-houses. A lady at Hampstead, who was in the habit of
day for the Broad Street water, was attacked by cholera and
ece, too, being on a visit to her, drank some of the water,
ards to her own house at Islington, and died there. On the
rcely any of the inmates of the workhouse in Poland Street,
s a separate well, were affected; and the disease also spared
yed at a Brewery in Broad Street, close by.

ns on a still larger scale were made, in 1854, in the south of
district containing a population of at least 300,000 persons,
ith water partly by the Lambeth Water Company, conveyed
es at Ditton, partly by the Southwark and Vauxhall Company,
as from the same river at Battersea. What rendered these
eculiarly conclusive was the fact that over a large area the
two companies ran side by side, each feeding some houses and
rding to the arbitrary preference of owners or occupiers at
when there had been an active competition for custom. Dr
detail, throughout the area in question, from street to street
to house, and he found that, during the last four weeks of
ut of three hundred and thirty-four fatal cases of cholera,
hundred and eighty-six in houses supplied by the Southwark
Company, twenty-two among persons who obtained water
ping a pail into the Thames, but only fourteen in houses
ly from the Lambeth Company. It is to be noted, however,
r of houses supplied by the Southwark and Vauxhall Company
n that of the houses supplied by the Lambeth Company, in
f forty to twenty-six. As the epidemic continued, the differ-
lera death-rate between the customers of the two companies
hough it still remained very striking. Bethlehem Hospital,

the Queen's Bench Prison, and other institutions on the south side of river which had deep wells, scarcely suffered at all from the disease.

In 1865 and in 1866 further evidence was collected bearing in the s direction. In 1866 the parts of the metropolis mainly affected were eastern districts, and Mr Netten Radcliffe, who investigated the matter the Privy Council, found that there was a great preponderance of c among persons whose water, supplied by the East London Water Compa had passed through the reservoirs at Old Ford, whereas comparatively cases occurred among those who received the water of the same Comp pumped directly from the filtering beds at Lea Bridge into the mains. difference was far from being as conspicuous as in South London du 1854, but one must bear in mind that among the poorer classes very m eat and drink and pass their days at a distance from the houses in w they are said to live. Moreover, at an early period of the epide a notice was issued, warning people not to drink any water which not previously been boiled, and it is worthy of notice that from the week in which this notice appeared the epidemic began to decline. A p of particular interest is that, assuming the reservoirs at Old Ford to h been in some way concerned in causing the disease, one can account for entrance of the cholera poison into their water; for part of it was someti drawn from two reservoirs which communicated freely with the river Le soakage, and this part of the river was, in fact, a canal with locks, received so large a quantity of sewage, that it was little better than a cess Now, shortly before the epidemic in East London began, a man and his w living in Priory Street, Bromley, near the banks of the Lea, had die cholera, and their evacuations had entered the river about 600 yards be one of the open reservoirs.

In the previous year, 1865, there had occurred in an Essex vill Theydon Bois, a most remarkable local outbreak of cholera, which illustr in a striking manner how insidious its propagation may be. Between J and November the disease seems to have been several times introduced Southampton by persons who arrived from the Mediterranean ports w it was then prevailing. Whether it was carried from this town du August or September to Weymouth or Portland or Dorchester, or whethe reached either of these places in some other way, was never ascertained. so much is certain; that a gentleman and his wife, visiting these places (but Southampton) in September, contracted diarrhœa at one or other of them, this, in the case of the lady, developed into fatal cholera after her retur her home at Theydon Bois on September 25th. On the 30th, while was still collapsed, one of her daughters was attacked and died in a few ho The same night a serving-lad in the house was seized and barely escaped his life. Altogether, in a fortnight, eleven persons within a narrow ci father, mother, grandmother, two daughters, son, doctor, foot-boy, m labourer, and countrywoman, fell ill, and only three of them recove Now, the drinking-water of the house all came from a well beneath scullery, and into that well there was habitual soakage from the water-cl

Soil-water theory.—The "soil-water" or "ground-water theory" of Pet kofer is that cholera never prevails epidemically where the soil is imperme to water, or where the level of the soil-water is not liable to fluctuations. brings forward several instances in which districts seated upon hard escaped, while adjacent towns built upon alluvium suffered. Some appa exceptions to the rule he accounts for, more or less satisfactorily. T

thirty miles. His wife and some other persons who visited him were sei on the following day. Presently it was found that his sister had died cholera a fortnight previously at Leeds, and that her wearing apparel h been sent to Monkton in a box which had been opened by him the even before he fell ill. During the illness his mother, who lived in a healt village five miles off, came to attend him, washed his linen, and after t days set off to return home, but was attacked on the road and had to conveyed to her cottage. Not only did she die, but her husband and daughter likewise.

In 1866 Parkes attributed an outbreak of cholera in Southampton mai to an atmospheric effluvium disengaged from sewage, which was constan being pumped up by a steam engine, and sent churning down an o channel for some eight or nine feet.

Altitude and climate.—There are still to be mentioned certain conditi which seem undoubtedly to influence the diffusion of cholera, however direct their operation may be. Dr Farr laid down a "law of altitude," least for London, showing that the incidence of the disease upon the popu tion varied inversely as the height above the river Thames. This, howe is but an expression of the fact that on an average persons living at a level are affected by the causes of cholera in larger numbers than pers living at a high level. Sometimes the case is reversed; thus Lebert s that throughout the epidemic at Zürich in 1855 the upper parts of the to suffered more than the rest. The circumstance that in Europe cholera never been known to prevail at an elevation of more than 600 or 800 mè above the sea may be set down to the absence of the conditions required its development; in other quarters of the world it has raged at altitudes 2000 to 2500 mètres. In temperate climates the summer and the autu are the seasons most favourable to it. It often dies out as winter approac to reappear in the following year; but in Russia, in 1830, it withst extreme degrees of cold.* Cholera appears never to have invaded Austr the Cape Colony, or the South Seas.

Diagnosis.—To recognise cholera in its well-marked forms is sel difficult. Almost the only morbid state which can be mistaken for it is produced by the poisonous administration of arsenic. Lebert relates Louis actually committed this blunder in regard to the Duke of Chois who killed himself with arsenic the day after his arrest for the murde his duchess. At that time, in the summer of 1847, the disease was prevailing in Paris. There is therefore good reason for bearing in mind a crafty person might take advantage of an epidemic to give poison with little risk of being suspected.

To distinguish the slighter effects of the virus of cholera from ordi diarrhœa is often quite impossible. Under the name *cholera nostras*, or *ch Europœa*, writers describe an affection of which the symptoms are ident with those of the specific disease (called by them *cholera Asiatica*), but wh differs from it in being scarcely ever fatal and in generally occur sporadically. A typical instance occurred at Guy's Hospital in 1865,

* The remarkable distribution of cholera in its visitation of England 1848–6 spread, ingravescence, and decline in the several towns it attacked, are described, and bearing on its ætiology as then appreciated impartially discussed by the late Dr Baly Dr (now Sir William) Gull in their 'Reports on Epidemic Cholera' to the Royal Co of Physicians, 1854.

corded by Wilks in the 'Medical Times and Gazette' for acksmith's hammerer, aged thirty-three, was at work as on May 25th, when he was suddenly seized with profuse ging. He was admitted collapsed, with cold breath; he had ks and in the legs; the evacuations and the matters vomited ce of rice-water, consisting of an alkaline liquid, with flocculi e recovered in about twenty-four hours. Dr Wilks added he saw one or two such cases, but seldom so early in the o be observed however, that at the very time when this l, an epidemic of cholera was approaching England; and, e as it may seem that an isolated case should spring up in eeks before the commencement of the local epidemics at at Theydon Bois, the possibility of such an occurrence l. At any rate, no case of so-called "English cholera" llapse, rice-water stools, and cramps) seems to have been y's Hospital since 1870; and it is certain that when the se in 1831 Sir Thomas Watson, the elder Dr Babington, hysicians of experience, declared that they had never "met mplaint before." However, it is undesirable to call any xcept that which comes as an epidemic from Asia, and ht never to call attacks of diarrhœa, in infants or even raic" merely because the symptoms are severe.

his is less favourable in children and in old people suffering in adults or in middle-aged persons. The mortality, which ulation generally averages about 50 per cent. or a little ng the very young and the aged to 70 or 80 per cent., ng adults it may fall to about 40 per cent.

n 1866, of 130 cases at the Meath Hospital 71 were ir Patrick Dunn's Hospital, 85; and of 197 at the Mater pital, 106.

f 21,519 patients in Italy, 11,563 died. In the following 338,685 cases of cholera were officially reported in Spain, 620 were fatal.

more than usually dangerous when it affects drunkards or eady sick or weakly. In an individual case the degree of greater prognostic importance than the amount of purging. mic diseases, the earlier cases are far more often fatal than when the pestilence is subsiding. At Calcutta, in 1850, lity was 47 per cent., but among the earliest cases it was among the latest only 25.

afforded by an attack of cholera against a subsequent one he slightest. Cases are not infrequent of persons who have epidemics, and some have died from the second attack. e parts of the East Indies where cholera is endemic, one ffords no immunity from a second, but seems scarcely to ty. All that can be said is that cholera does not predispose as erysipelas undoubtedly does.

he *prophylactic measures* which should be adopted when a ned or actually attacked with an epidemic of cholera were ed by Mr Simon and his colleagues in 1866, and will be

found detailed in his ninth 'Report.' They are generally such as might anticipated from what is known of the ætiology of the disease. Mr Sim attached great importance to the avoidance of all such food as is apt set up diarrhœa—half-fermented beer or wine, meat or game no longer fr or not completely cooked, stale fish or shell-fish, vegetables or fruit l gathered or badly kept, and the like. He deemed it unwise to take pu tive medicines, except of the mildest kind; and, in accordance with alm every other observer, he insisted on the necessity at such seasons of ch ing looseness of the bowels, however painless and trivial. Dr Bristowe al maintains that the diarrhœa which so commonly prevails when choler epidemic is neither more nor less likely to pass on into that disease, whet it is left alone or encouraged by purgatives; nor will he allow that, if i really premonitory of cholera, it can be arrested by any medicine whate Dr George Johnson's theory, that the purging of cholera is an effor nature to get rid of the *materies morbi*, and should therefore not be chec but even encouraged by administering mild laxatives like castor oil, does appear to be accepted by any other physician.

Most writers recommend that the initial diarrhœa should be treated v opium in considerable doses, and with astringents, such as acetate of l nitrate of silver, catechu, or chalk. In India Dr Goodeve says that i usual to give from one to five grains of calomel with the first two-g doses of opium, and to check the diarrhœa as much as possible.

When *collapse* has developed itself the administration of opium astringents is believed to be useless, or even worse than useless. state of the circulation is now such that absorption is nearly arrested; drugs introduced into the stomach in successive doses may, if not vomi accumulate there so as to produce ill effects at a later stage, should reac happily occur. For the same reason alcohol must be used with g caution, if at all. Dr Goodeve says that its admissibility depends upon effect on the pulse. If a dose of weak brandy-and-water causes the puls revive ever so little, there is no harm in continuing to give the stimulan small quantity. In any case ether or ammonia may be used, prop diluted, unless sickness is produced. But Dr Goodeve finishes his rem upon this point by saying that many cases in which there is extreme coll come round by themselves, as well as, if not better than, with stimula Ice-cold water may be freely allowed to patients with cholera, not indee such large quantities as their morbid thirst might lead them to swal but by tablespoonfuls or wineglassfuls at a time. Lebert would also effervescing draughts made with carbonate of soda and with lemon ju and at the London Hospital in 1866 a "saline lemonade" was emplo with apparent advantage.

There seems to be no objection to administering a dose of morp subcutaneously if the cramps are very severe. Or an occasional whi chloroform may be given by inhalation. It may also give relief to rub p chloroform or turpentine into the painful parts. The burning sensa at the epigastrium may be alleviated by applying a mustard plaster.

The limbs should be kept wrapped in warm flannels, and hot bot should be placed in the bed, but not in contact with the patient's s At the London Hospital, in 1866, baths at a temperature of from 98 104° were employed in about one hundred and thirty of the worst ca and with most marked effects. For a few seconds after immersion th was commonly difficulty of breathing, and sometimes an unpleasant se

But in less than a minute a favourable action generally ; the pulse returned, or (if it had been perceptible before) d quicker; the patient grew less distressed, ceased to moan pain, and sometimes fell into a quiet slumber. In many ppeared to be the direct consequence of the bath ; but in ymptoms returned unaltered.

ce at the London Hospital seems also to have been not un- practice of injecting a warm saline solution into a vein, e in an apparently hopeless condition from cholera collapse; ses so treated by Mr Little there were four recoveries. , however, consider this treatment incapable of producing ood result. The immediate effect of an injection is admitted be often marvellous; a person speechless, and almost dead, sciousness, sit up, and talk; and the pulse may become ll. But in most cases the improvement has been only symptoms soon return and end fatally even though the be repeated. Still, as Sir Thomas Watson observes, even y amendment may sometimes be of great importance, mple, a will to be executed. The fluid used by Mr Little grains of chloride of sodium, six grains of chloride of potas- s of phosphate of soda, twenty grains of carbonate of soda, s of pure alcohol, to twenty ounces of distilled water. Eight oduced at a time, the temperature being about 110°, and thirty minutes were occupied in the operation. In three on was repeated, and one of them ended successfully.

n begins, the management of the case of cholera continues care and caution. A little beef-tea or chicken broth may n small quantities at intervals, or some light farinaceous el or arrowroot. Should vomiting continue, it may often dose of opium, or by a blister applied to the epigastrium. it is necessary, for a time, to have recourse to nutrient ake up for the loss of salts from the blood, carbonate of e of sodium should be given in moderate quantities. If mes dry and brown, a powder containing two grains of m cretâ, half a grain of ipecacuanha and two and a half s powder was found useful at the London Hospital. When urine continues during reaction, the patient should be drink freely; he may take a drachm of liquor ammoniæ e or ten drops of tincture of digitalis, every two or three ard plasters or cupping-glasses may be applied to the loins.

ERYSIPELAS*

erysipelas—Complications—Sequelæ—Diagnosis—Prognosis—Treatment

HITHERTO all the diseases discussed have agreed in the essen features of the group called Specific Fevers, and each has been easily defi and separated from any other malady. But now we come to less ea limited categories.

Erysipelas and Diphtheria have both been the subjects of much con versy as to the extent to which the name should apply, and as to "specific" character of many cases. The difficulty arises from the pro nence of the local lesion and its likeness to non-specific inflammation.

Erysipelas is frequently mentioned by Hippocrates as a form of ac inflammation of the skin, and the term has never since been lost in med literature. There have, however, been great differences of opinion a what affections should be included under this name, and particularly to the relation of certain local inflammations to the specific fever.

Some physicians, especially in France, have been anxious to separat "medical erysipelas" of the face and head from the cases seen in surg practice, of erysipelas attacking the limbs and the body after injuri and in England this distinction received Sir Thomas Watson's supp Another question, at one time much discussed, was the relation betw erysipelas and erythema. The latter term is applied to various forms superficial dermatitis, which will be described in the last section of t work; but there can be no doubt that it has sometimes been applied light cases of erysipelas.

Many English surgeons regard as "erysipelatous" almost every form spreading inflammation of connective tissue, even including diffuse suppu tion of the post-peritoneal structures after operations on the rectum. T view is strongly objected to by Volkmann and other German writ They will not even allow that we are right in describing as "phlegmon erysipelas" cases of suppuration or gangrenous inflammation, attended w intense redness of the skin, but also affecting the subcutaneous and int muscular textures.

Lastly, the epithet "erysipelatous" has been applied by some obstet physicians to the septic peritonitis of puerperal women.

Pathology.—All these questions must ultimately be settled by ætiologi considerations. Erysipelas is a contagious disease. Of its propagation

* *Synonyms.*—Febris erysipelatosa, Ignis sacer, Rosa, the Rose, St Anthony's fire— Erysipèle.—*Germ.* Rothlauf. 'Ερυσίπελας is a classical Greek term.

l examples were recorded many years ago by Dr Wells, of spital, the celebrated author of the 'Essay on Dew.' For a nental observers disputed the possibility of such an occur nann cites more than a dozen cases in proof, and it is now tted. Perhaps the most striking series of recorded cases fore the Paris Academy in 1864 by Dr Blin. One of the Lariboisière Hospital had under his care two patients rysipelas, when he was himself seized with it. A medical ise visited him and fell ill after returning to that place, case of the disease then existed. That gentleman's servant nd also a relative who came to see him, and who lived in od. The latter gave erysipelas to his wife, and three other family who were repeatedly in contact with them ess suffered in their turn. From this family the disease sters of mercy, and they carried it to their home and gave nan who attended them. Lastly it passed from him to his

not only a contagious, but also a *specific* disease, in the always dependent upon the entrance into the body of a om without. It is a great mistake to suppose that the æmia, necessarily becomes prevalent wherever surgical owded together under unfavourable conditions. In the the Austro-Prussian war of 1866, and in the Franco- 1870 repeated examples presented themselves of hospitals possible to keep healthy, and yet erysipelas failed to appear. nd, there have been many instances in which it has pre- lly, sometimes in a single ward or in several wards of some metimes in various institutions of a city or town. Whether as an epidemic over the inhabitants of an entire district, ue, and the exanthemata, is more doubtful. Between 1841 said to have been the case in various parts of the United Volkmann and Hirsch are of opinion that the disease was rom erysipelas and allied rather to diphtheria.

l the poison of erysipelas often clings to particular wards, icular beds, with extreme obstinacy. Mr Savory, in the n.' for 1873, remarks that at St Bartholomew's, during a which occurred there, the disease almost always, in passing to another, attacked the nearest patient who had an open he late Mr de Morgan, in 'Holmes' System of Surgery,' hority of Dr Goodfellow, a most extraordinary instance in in regular order throughout a ward of thirteen beds to ient in turn, going down one side of the ward and then up

The following case was observed by Mr de Morgan ing been found at the Middlesex Hospital that patients djacent beds with a window between them were particu- ttacked, the suspicion arose that this might be due to the ustbin in the area below. It was cleaned out and there cases. But two years later the disease reappeared, where- nd that the dustbin had again become foul, although no ium from it could be detected. The adoption of the same ore rendered the beds again healthy. In this instance it e doubted whether the impure air actually conveyed a

poison to the patients, or whether it merely predisposed them to attacked. But no such doubt seems to be admissible in regard to anot set of cases, recorded by Dr König, of Rostock, in the 'Arch. d. H kunde' for 1870. In the hospital of that town a small epidemic erysipelas was clearly traced to infection from the cushion of the operat table. This cushion was deeply discoloured with blood, and from the it was removed no fresh case occurred. The cushion was now soaked water, and a brownish solution was obtained which was inoculated u two rabbits, with the result that one of them had an affection which clo resembled erysipelas. The contagion is undoubtedly conveyed not o by direct contact with a patient but also by fomites, probably by the and there is reason to believe by the dead body.

Dr J. Orth, of Bonn, recorded in the 'Arch. für experim. Path.' 1873, a series of experiments by which he has demonstrated the possibi of infecting rabbits by the subcutaneous injection of fluid taken from erysipelatous bulla in man; he also transmitted the disease from rabbit rabbit by inoculating with liquid from inflamed and œdematous parts of skin and even with blood from animals already infected. That erysip can be conveyed in a similar manner from one human being to another se to be established by an old observation made by Doepp, who vaccinated n children with lymph from a child who on the following day fell ill w erysipelas; all were attacked by the latter disease.

Orth found motionless micrococci in the infecting fluid with which made his experiments on rabbits, and he succeeded in producing erysip by inoculating animals with micrococci that had undergone artificial cu vation. The presence of such organisms in erysipelas had, indeed, b previously demonstrated by Lukomsky and by Hüter, not only in tiss affected with the disease and in the œdematous fluid which saturates th but even—in small numbers—in the blood. Subsequent investigations Fehleisen and Koch in 1883 have confirmed the constant presence *Micrococcus erysipelatosus*. Lastly, a cancerous tumour has been injected w a pure cultivation of this microbe, and erysipelas followed. It often is fou as a streptococcus in the thin serum of a bulla and pus of an abscess—and the lymph channels; but is absent or sparingly present in the blood. It is cessively minute, smaller than the granules observed in the lymph of vacci

Thus all the tests enumerated in p. 13 seem to be satisfied, and may conclude that erysipelas is a "specific disease."

Phlegmonous erysipelas.—We must now revert to the question of relations between the various forms of disease that have been included un the name of erysipelas. As regards the "spreading inflammation" f mentioned, Volkmann himself admits that acute diffused suppuration, sev diphtheria, or even puerperal fever, when introduced into a hospital free fr erysipelas, often forms the starting-point of an outbreak. He cites a case Pujos, in which a man who had a severe gunshot wound of the foot die erysipelas, or, as he says, "pseudo-erysipelas," which in several places passed on to gangrene. A brother, who attended him, was attacked w erysipelas of the face, and so was a nurse; and several other persons bec affected with phlegmonous inflammations. Volkmann adds that those attend upon cases of puerperal fever often become the subjects of facial sipelas. Such occurrences are the more striking because it is admitted all hands that contagiousness is a far less conspicuous feature of erysip than it is of many specific maladies. But, after all, it is quite possible

without giving up the view that erysipelas is a specific be that there are certain cases of puerperal fever, or of puration, or of diffused phlegmonous inflammation, which to the poison of erysipelas, and that these cases alone are ucing it in their turn. Or it may be that just as in culti- nts there is great difficulty in keeping fluids free from nination with foreign bacteria, so the discharges from dis- living patients afford a favourable nidus for the growth of which may have no relation to the disease from which these ing. In phlegmonous erysipelas it is quite possible that *es aureus* may be mingled with *Streptococcus erysipelatosus*.

y it was thought that erysipelas of the face and head, as differed altogether from the surgical affection in one very t, namely, in appearing upon the unbroken skin, inde- wound or abrasion. Trousseau, however, pointed out that om some slight breach of surface, as from a suppurating gle of the eye, which the patient may have scratched, or czematous eruption on the nose, or from a fissure at the uth, or from a herpetic affection of the fauces, or even from o a decayed tooth. This view has since been adopted both d by Zülzer. A most careful record of observations for the g its correctness was made by König. Among twenty-nine as of the face or scalp which occurred in the inmates of a ain, fifteen were traceable to previous injury of the affected mainder no such starting-point could be found, but in all of as the seat of the disease, and in many of them it was so en the patient was first admitted that no complete examina- de.

ion, of course, is that the contagious microbe of the disease spot which afterwards becomes the seat of erysipelatous in- hat infection of the blood is secondary. The complete want he distribution of the cutaneous affection may be mentioned ong argument in favour of this view.

Watson mentions cases in which the incubation of erysipelas a week, and Murchison states that in his experience it was ee or four days. In Fehleisen's experimental inoculations ubation was from fifteen to sixty hours.

ason to believe that during this time local changes are , although there is no obvious inflammation of the skin. go been noticed by Frank and by Chomel that the develop- las of the face is often preceded by pain, tenderness, and cervical glands; and the late Mr Busk, after close observa- number of cases, was convinced that this was an invariable haps inflammation is already going on, but the lymphatics udation as fast as it appears. The possibility of such a he inflammatory process is expressly admitted by Cohnheim. ion cases, too, seem to show that the infective microzymes ust at the same time be multiplying themselves locally, for bered that the lymph which conveyed erysipelas was taken a child in whom the disease did not appear until the follow- here any difficulty in imagining that the blood may even at

this early period be contaminated both with microzymes and with inflam
tory products, whether by direct absorption through the veins or by tra
mission through the lymph-glands and onwards through the thoracic du
And thus it is quite easy, without supposing a primary infection of
blood, to account for the production of constitutional symptoms, which se
to be premonitory of the local affection but are really not so. Watson s
that before the outbreak of erysipelas the patient often feels ill, shive
feeble, languid, and often drowsy; that his pulse is very frequent; that
may suffer from nausea, vomiting, and even diarrhœa. It must be add
however, that he speaks of sore-throat "as an early, and almost a consta
accompaniment of the complaint." Volkmann declares that in the ma
cases in which he has watched the development of erysipelas in patien
already in hospital, whose temperatures had been systematically obser
for some time previously, he has never seen any prodromal symptoms wh
ever. In his opinion, whenever they seem to be present, the fact really
that the local affection has already begun; but in some deeply seated pa
so that it remains undiscovered. Now, Trousseau has maintained th
erysipelas of the face often starts from the mucous membrane of the pal
and fauces, and reaches the skin by passing outwards through the nostr
It is obvious that such an affection might well account for the early swell
of lymph-glands already alluded to.

A case in point came under the author's observation in 1882. A m
who had had jaundice for some time was admitted under my care on June 24
His temperature was then 105°. He said that his febrile symptoms had beg
with a slight rigor on the evening of the 22nd. There was no evidence
pylephlebitis or other local affection of the liver to account for the pyrex
On the 26th the end of the nose was found to be red, and a blush
erysipelas soon spread over the face. It was then remembered that when
first came into the hospital he complained of sore-throat, and that on t
25th the clinical clerk had noticed the submaxillary glands to be swollen.

Onset and exanthem.—The onset of erysipelas is usually sudden, and it
often marked by rigors, but in persons already suffering from a febrile illn
the increase of pyrexia may be comparatively trifling. The late Dr Woo
man (in his translation of Wunderlich's work) remarks that even in adu
epileptiform convulsions are not uncommon. The temperature may rise
twelve hours to 104°, and usually reaches its *fastigium*, which may be at 10
or even 106°, within the first two or three days.

In some cases severe febrile symptoms may set in and last two or thr
days before the rash appears. This "prodromal" period between that
incubation and the appearance of the exanthem is exactly like those
scarlatina, measles, and smallpox.

Usually, however, as soon as the fever sets in, or within a few hou
some part of the skin, usually near the angle of the eye or the ala of t
nose, begins to burn and tingle and becomes red and swollen. The redne
rapidly deepens into a crimson blush, which fades under pressure, but retur
as soon as the pressure is removed. Its extent increases until in a day
two it may cover the whole of the face. Where it is spreading, it has
sharply-defined, raised border, beyond which, however, projecting process
advancing into the subcutaneous tissue may be felt with the finger. On t
other hand, where it is stationary, its edge fades off gradually into th
healthy skin beyond. There is extreme swelling, especially where the sk
is loose, as upon the eyelids; these become converted into rounded pu

is impossible to separate them, so as to get a view of the atures are so altered that the patient cannot be recognised. se and shining, though it may be made to pit by keeping e on it. There are often a few scattered vesicles, or blebs, a large size; Volkmann confirms a statement originally that minute vesicles can always be seen with a lens.

four days the disease may go on spreading, until, if it began the head, it may cover the whole surface down to the root olkmann, however, remarks that the chin always remains The conditions which determine its advance in one line ier have lately been carefully studied by Pfleger, whose y Zülzer with approval. It would seem that this depends arrangement of the subcutaneous connective-tissue bundles; interlace, so as to form rhomboidal meshes, but these are or oblique, whereas upon the chin their direction is vertical. tains that wherever the skin is tied down to the deeper of erysipelas is retarded or arrested, as for example, along ilium and Poupart's ligament. Erysipelas of the face and nds far upon the chest; but when the disease begins upon n a limb, it may spread until it has covered the whole body. ancing, however, it subsides in the parts first attacked while o elsewhere; hence it is never a universal or even a sym- m. Beyond an affected area small islets of redness may not een, but these are always connected with it subcutaneously. es that erysipelas never gives rise to two or more patches at ne another: it may, indeed, happen that in a case of double stumps are affected; or that in a case of erysipelas of the breaks out a few days later round a pimple on the leg; ould be regarded as multiple attacks of the disease.*

cium.—During an epidemic of erysipelas in a hospital, it is ing for cases of sore-throat to occur, which are evidently re, but in which the skin remains unaffected. An account ne disease has been given by Cornil, based upon a study of He describes a shining, purple-red, œdematous swelling of etimes accompanied with the formation of bullæ. The e no part in it. The lymph-glands below the jaws and in h enlarged. There is considerable pain in swallowing, and use flow of saliva.

The minute anatomy of erysipelas was first studied by more recently by Volkmann and Steudener. In the dead is so little marked, from the redness and swelling having y disappeared, that Volkmann evidently was surprised at er strata of the cutis, as well as the subcutaneous tissue, enormous numbers of granular leucocytes. He gives a icroscopical appearances, in which the cells are seen packed ide. In the more superficial strata, they are, however, aringly. The structure of the bullæ was investigated in by Dr Haight, of New York. He found them to be divided

* the case of a child in whom, after a wound of the temple, redness first subsequently upon the chest, the right arm, and the left wrist in turn; t the morbid process might not have been continuous over the back of —C. H. F.

into loculi by irregular septa which are made up of cells of the rete, dra out into long, spindle-shaped and branching processes. The fluid of the bu of course contains numerous leucocytes, and is often converted into p The micrococci of the contagion are found in the fluid that fills the vesi or blebs, and in greater numbers in the lymph-spaces of the affec cutis.

Symptoms.—While the local process is thus running its course, the pyre continues, the temperature rising and falling irregularly, or remaining nearly the same level. According to Dr Reynolds it is frequently lower the evening than in the morning. The pulse is quick, and it is gener soft and feeble; it may be dicrotic or intermittent. There is usually m or less delirium at night, and sometimes violent maniacal excitement. T patient often complains of headache, sleeplessness, and irritability of si and hearing. He has no appetite, and is thirsty; the tongue is thic coated; he has nausea and may vomit repeatedly; there is often diarrh with extremely fœtid stools. The urine is scanty and commonly albumino and may even contain casts and blood.

The duration of erysipelas is variously stated by different writers; it in fact, very uncertain. Billroth says it seldom reaches fourteen da Volkmann puts it at about six or eight. When the disease wanders o the body and limbs it may run on for weeks, or even months. The f defervescence is usually sudden, the temperature falling to the normal p in a few hours.

The subsidence of the exanthem is also rapid, and then the s becomes pale and flaccid, and shrivels; at the same time other parts of surface may be at the height or the beginning of the morbid proc Volkmann and Steudener have investigated the histology of this stag the process; they find that in the subcutaneous tissue the leucocytes appear with extraordinary rapidity, breaking down in a few hours int granular *débris*; in the superficial layers of the cutis they remain visibl little longer, but within a day or two all signs of tissue changes vanish. the meantime the vesicles or bullæ have dried up into yellowish crusts. cuticle subsequently desquamates, and is detached either in flakes or s branny powder. When the scalp has been the seat of the disease the h falls out for a time, but is soon reproduced.

But it does not always happen, even when a case of erysipelas e in recovery, that the local affection subsides thus favourably. Delic parts, such as the eyelids, the prepuce, or the labia sometimes slough, consequence of the tension to which they have been subjected. In ot cases, when the swelling has gone down, abscesses form here and th beneath the skin, and need lancing. Suppuration of the swollen lym glands is a very exceptional occurrence.

Recurrence.—Erysipelas seems to have no tendency to protect agai its own recurrence in the same individual, or rather, as Fehleisen found, protection is only for a very short period. In surgical wards it used to no uncommon thing for a patient to have two or even three success attacks while a large wound was healing. Women sometimes have the dise once or oftener every year. In such cases it is often directly excited cold, as by exposure to an east wind; but Zülzer and other writers say t it almost always has a starting-point in some local affection of the face the nasal mucous membrane, the ear, or the lachrymal passages. In co of time this "recurrent" or "habitual" erysipelas leads to a persist

nduration of the nose, ears, or eyelids, which greatly deforms

ın, however, declares that metastatic abscesses were present
d to one half of all his fatal cases; but he adds that every
ıts also had a severe wound, and so there may have been an

embolic and infectious process going on independently of the spec contagion.

Sequelæ.—Scars only follow the phlegmonous form of erysipelas, l when repeated attacks affect the same part, a chronic hypertrophy of t skin with œdema durum of the subcutaneous tissues and lymphatic engor ment sometimes follows: and thus the condition known as elephas of t legs and the scrotum is often the result of recurrent erysipelas.

Various affections of the eyes have also been observed to follow an atta of erysipelas—opacity of the cornea and even optic neuritis.*

It is very rare for the febrile albuminuria which is so very frequen symptom of this malady to persist, so that Bright's disease is scarcely ev to be traced to this origin.

Diagnosis.—The recognition of erysipelas is easy, if we leave out consideration the theoretical doubts as to the relation which it bears, the one hand, to phlegmonous dermatitis and diffused suppuration, and, the other hand, to certain forms of erythema. Zülzer speaks of the œdem tous form of anthrax as being sometimes mistaken for it. There is anotl disease, which is often mistaken for erysipelas, and that is herpes zoster the forehead and face.†

Prognosis.—This is generally favourable for the cases of erysipelas th come under the care of physicians, except in old people and in infan in the latter it not infrequently appears at the umbilicus, and proves rapi fatal. Even in surgical practice recovery so generally takes place that it difficult, as Dr Wilks has remarked, to understand how it came to pass th the common form of certificate submitted to a magistrate in cases of slig wounds used to be that there was no danger, "unless erysipelas shou ensue." It may be, as he suggests, that what really was pyæmia was oft set down to erysipelas. There can be no doubt, however, that erysipe itself was once far more fatal, at least in certain institutions, than it is present; thus Volkmann says that in the old Hôtel Dieu at Paris it wou often happen that the majority of surgical cases attacked by it ended death. But probably much of the difference lies in the fact that patien suffering from erysipelas are now well supplied with beef-tea and wine a brandy, instead of being bled and leeched and kept upon low diet.

Even in adults a fatal termination is apt to occur when the patient h chronic disease of the kidneys, or has been intemperate, or is otherw broken down in health. Before death the temperature usually rises to great height, and sometimes it goes on rising for a short time afterwards.

Treatment.—In this country we believe that the tincture of steel has marked influence in checking erysipelas. Mr de Morgan from his experien at the Middlesex Hospital, spoke most positively of its efficacy in reducing t

* See on this point, however, an abstract of numerous observations made in Rus which appeared in the 'London Medical Record' for November, 1888, p. 473.

† Only a few weeks ago I found lying in the hospital a youth whose face was cove with flour, through which a diffused redness was visible, while the eyelids were enormou swollen. The first glance, however, showed that the affection scarcely, if at all, passed middle line of the forehead; and according to the account which the patient himself ga it had begun with an eruption of vesicles. I therefore made a confident diagnosis that case was one of zoster, and dropped atropine into the eye, on account of the danger iritis. At my next visit, the redness and swelling had disappeared without desquamati and the vesicles had dried up into characteristic dark brown eschars.—C. H. F.

isease, so that it subsides in from two to four days, instead or ten days. He gave at least a drachm or a drachm and sometimes as much as an ounce and a half or two ounces. it is more usual to give quinine.

comes under observation at the very commencement of the is believed by many to be useful. Dr Ringer believes that red at this period may cut short the attack. Given after the appeared it usually brings down the temperature but has nd possibly may do harm.

y years ago Mr Higginbottom introduced the practice of of silver round the circumference of a patch of erysipelas, its spread might in this way be arrested. This was termed ethod, and there are still some who have faith in it, nn, who prefers the silver salt to the tincture of iodine, een suggested with a similar object. The part must be first with soap and water, or with a solution of soda or potash, so at from its surface. It may then be brushed over with a trate in from eight to ten parts of distilled water for a inches round the reddened area, on all sides of it. and Sequelæ—Albuminuria—Paralysis—Prognosis—Treatment.

ABOUT the year 1855 attention was drawn in England to the preva
of an epidemic disease, resembling scarlet fever in being generally atte
with an affection of the fauces, but differing from it in the charact
that affection, and in the absence of a rash. Many accomplished physi
including Addison, declared that they had never seen this disease be
and although a search into medical literature brought to light se
instances of its occurrence, both sporadically and in an epidemic form
the fact remained that, at least within the present century, it had
previously spread over any considerable part of the country at the
time. In France it had been well known for several years, and had
carefully studied in 1818 by Bretonneau, of Tours, who had given
name of *diphthérite* (διφθέρα = leather or membrane). In fact, the epi
of 1855–57 was introduced from France, and was known as the "Bou
sore-throat."

It is impossible to distinguish, in the accounts of the ancients, bet
the angina of scarlatina and that of diphtheria, or even of syphilis.
undoubted epidemics of diphtheria occurred in Spain in the sevent
century, and were described in 1614 by Mercatus, physician to the
Philip II and III, and in 1670 by Heredia, physician to Philip IV
spread to the Spanish provinces in Italy, and was epidemic at Napl
1618, when it was described by Cortesius (1625), Aetius Cletus (1
and the celebrated Danish anatomist Bartholinus (1646). It pro
appeared in Edinburgh in 1733, according to Fothergill, from whose tr
on 'The Putrid Sore-throat attended with Ulcers' the above referenc
taken. In 1746 there was an epidemic at Bromley, in 1747 o
Greenwich, and in 1749 one in Cornwall, which was described i
'Philosophical Transactions' by Dr Starr. Its reappearance as an epi
in South Wales in 1849 was recorded by Mr J. D. Brown.

There is reason to believe that the *cynanche maligna* of the older w

y cases of scarlatina anginosa, but also some which would as diphtherial.

this disorder has constantly prevailed with more or less ng up here and there in different districts of England, as countries. Numerous investigations have been made as to ode of propagation, but in regard to many points doubts particularly about its relations to certain other diseases. which is now almost universally applied to it is Diphtheria. n, has indeed proposed to term it "Cynanche contagiosa;" ms to have no chance of being generally adopted, although dly would avoid many sources of error and confusion, by anyone who may read Senator's paper in the second n Clinical Lectures, published by the New Sydenham

pathology.—As the term diphtheria implies, the essential sore-throat is the presence of a membranous substance, nore or less extensively over the tonsils, the uvula, or other nneau, and his followers, great stress was laid upon the stance could be detached from the mucous membrane be- the latter was then found to be only reddened and t the utmost slightly excoriated. They pointed out that layer, being of an ash-grey colour, often simulated very rance produced by sloughing of the parts it covered; and, lisease had long been known under the name of gangrenous ant sore-throat. But they declared that such appearances and that no considerable loss of substance occurred, still e sloughing. Finding, moreover, that in many cases the down into the larynx, they formed the opinion that the as "membranous croup" was only a form of diphtheria. vriters the subject has been developed in a very different ow, in the first volume of his well-known 'Archiv' (pub- distinguished between a "croupous" form of inflammation "diphtheritic" one. In the former, he said, the exudation e surface of the mucous membrane; but in the latter its the superficial layer of that membrane, which generally hing as the result of its presence. These definitions, being equent writers without a due comprehension of what pro- w's real meaning, have led to great confusion, which is o be cleared up. A good description of the characters of flammation," in the sense attributed to it by the great rlin school, is given by Rindfleisch in his 'Pathological makes it consist of an infiltration of newly formed cells ithelial connective tissue of the mucous membrane (the llowing an idea originally suggested by Buhl, he teaches nce of this infiltration compresses the blood-vessels, and so lation through the affected parts, brings their nutrition to a eprives them of life. As examples of such an affection, he nflammation of the urinary bladder that is set up by decom- nant urine, the more severe forms of dysentery, and the mation of the uterus and vagina which may occur imme- turition; and he points out that a similar condition may be

met with upon other free surfaces: upon the skin, as in the more destru tive kinds of variolous eruption, which lead to permanent pitting; a upon wounds, as in hospital gangrene. It must be admitted that all the forms of inflammation have characters in common, and deserve to be know by a special name (cf. p. 52).

But, if this view is to be taken of the distinguishing features of "dip theritic" inflammation, one sees at once that the disease "diphtheria" fin no place in it. Accordingly, Rindfleisch describes the latter under croupo inflammation, and by the name of "pharyngeal croup." He gives a very fu account, which the writer can confirm by his own observations, of the hist logical characters of the pellicles which are found upon the surface of t mucous membranes in what we call diphtheria. On the palate and tonsils says they consist, not of fibrin, but entirely of cells, which have undergo a peculiar glassy change, and have become fused together, so that a seri of little fissures alone indicates the original interspaces between the According to E. Wagner, these cells are all derived from the original ep thelial elements of the affected part. In the air-passages, on the other han Rindfleisch describes the pellicles as laminated, and consisting of layers cells which alternate at tolerably regular intervals with layers of a hom geneous substance, apparently fibrin.

Some writers have attached special importance to the fact that different affections of the throat there are great variations in the degree which false membranes adhere to the mucous surface. But these variatio depend mainly upon the *seat* of the lesion. As between the several diseas the distinction is valueless. The fact that in the very same case of diphther the membrane on the tonsils and that in the larynx differ essentially in the histology is of itself sufficient to show that our views in regard to the disea cannot be based on its pathological anatomy alone.

In the same patient we often find, after death, upon the fauces a thi grey, ragged and decomposing membrane, which bled and stank durin life—and the same characters mark the disease when it spreads from th palate and tonsils to the nares and the pharynx; on the posterior surface the epiglottis, in the larynx and the trachea, a thick, white, firm, an continuous layer with abundance of fibrin, along with leucocytes, but wit no blood-discs; and in the bronchial tubes very scanty shreds of membran with abundance of mucus and pus.

Moreover, in the fauces themselves, the morbid changes present wid variations of intensity. There is, in the first place, "*diphtheria sin diphtheritâ*," a variety in which the tonsils and uvula are merely reddene and affected with catarrhal inflammation without a "false membrane, but which can be plainly recognised as diphtheria, because it occurs in th same family simultaneously with the more severe forms. Even when mem branes are present, they differ greatly in extent and thickness in differen cases. Rindfleisch, indeed, speaks of the morbid process in the pharynx a being always insular, and as consisting of circumscribed milk-white spots, o an intensely hyperæmic base, which are never raised more than half a lin above the level of the mucous surface. But no physician who has had muc experience of the disease can be ignorant that in many instances the whol fauces, tonsils, and uvula are covered with a thick tough layer, which look like wash-leather, and may ultimately be detached *en masse*. In 1858, D Fuller exhibited to the Pathological Society a cylindrical cast of the pharyn four inches long, which had been ejected by a girl aged eleven. Indeed, i

nbranes are removed, or become detached, they may be and again. This is well known to all who have observed s of the disease; and Dr Burdon Sanderson vouches for it as s own observation in 1859. "At Crowle," he says, "I had of seeing an example of extreme rapidity of reproduction of ryngeal concretion; and I have notes of a case, in a robust gfordbury, watched with the greatest care and attention, in of the mucous surfaces the pellicle must have been renewed thirty times in the course of three or four weeks." This portant, because Rindfleisch expressly denies that false mem- palate or tonsils ever recur in the same place, unless they ped off before their spontaneous maturation; and Oertel (in Ziemssen's 'Cyclopædia') likewise limits the possibility of ion by arbitrary conditions. Another point on which ts positively is the frequent occurrence of ulceration, which, hat he observed, led to perforation of the palate; and he stance in which the tonsil and the arch of the velum were hat a continuous sloughing surface extended to the pharynx. erved that in cases which presented exactly the appearance he uvula and tonsils in a state of "putrid dissolution," and st detached—the fauces were found after all to be intact membranes at length came away; but all recent writers, both rman, admit that Bretonneau went too far in denying the ngrene.

e think, clear that the definition of diphtheria as a disease n the histology of the exudation, but on its pathology and natural history: in other words, less on anatomical than on aracters.

ic course, the infective power, the kind of fever, the effect s, and the sequent paralysis—these are the distinctive n mark the Boulogne sore-throat or Cynanche contagiosa or ther in the fauces or the larynx.

primarily local?—An important pathological question has dered—namely, whether the disease is from the first consti- ether Oertel is right in maintaining that it is originally ts the system secondarily. His chief argument is based between the results obtained in the experimental transmission the lower animals, and those which follow the inoculation glanders. In the former case, he says, the affection always at the spot to which the poison is applied; in the latter it s the nasal membrane, even when the contagious principle d beneath the skin.

f this statement is accurate, it leaves diphtheria in the s erysipelas and syphilis. There can be no doubt that a special tendency to attack the fauces, and that the fre- al diphtheria does not merely mean that the poison comes h this mucous surface more frequently than with any other. etimes when the affection has begun elsewhere the throat ily, apart from any direct extension of the morbid process. as admitted into Guy's Hospital with an affection of the oubtful nature, but before his death the palate and tonsils l with a false membrane, so as to clear up the nature of the

case; and in epidemics of conjunctival diphtheria, of which several ha occurred in Berlin, the fauces have occasionally been attacked.

Ætiology.—The first point to be insisted on is that diphtheria is contagio This, indeed, is not always an obvious feature of the disease as it is se in private practice; for if several cases occur in succession in the same hou one cannot say whether they all depend upon a common cause, or whet one has given rise to another. But when a patient suffering from diphthe is admitted into a hospital, it often happens that persons occupying beds the same ward are subsequently attacked. Sir William Jenner rela several instances in which patients sent into the country infected those w whom they came into contact. The epidemic in East Kent in 1856 w ushered in by a striking instance. "No case of diphtheria had ever be seen in Folkestone during my time," says Mr Eastes, "until Isabella W- aged 4¾, arrived from Boulogne on the evening of July 2nd, being then an advanced stage of the disease. She died on the following day. On t 6th, her sister, aged ten, was attacked, who had always resided on t East Cliff; another case occurred in the same house three days after, a they all terminated fatally." But the most conclusive of all argument furnished by the unhappily frequent instances in which a medical man h fallen sick with diphtheria, immediately after having had phlegm cough into his mouth or nose by a patient whose fauces he was examining; or af having used his lips to inflate his patient's lungs, or blow through a trach tomy tube. Oertel mentions by name five physicians whose lives were th sacrificed, among whom was Valleix, the writer on neuralgia. A lamental case of death from such self-devotion occurred in the person of a hou surgeon at King's College Hospital, and similar cases are not rare in oth hospitals. It was believed that the late Princess Alice of Hesse contract the disease by kissing her child who was ill of diphtheria. A case belongi to the same class is that of Dr Wiessbauer's child, who was attacked short after having put into his mouth a cannula that had just been removed fr the throat of a patient suffering from diphtheria.

It must, however, be admitted that even when the conditions see favourable, diphtheria sometimes fails to spread. Those in attendance up patients suffering from diphtheria have recklessly or ignorantly blown throu tracheotomy tubes for the purpose of cleaning them over and over aga without suffering ill effects; and Trousseau in 1828 and afterwards Pet actually inoculated themselves on the palate and tonsils with diphtheri matter, and were none the worse. There is nothing very surprising in the facts, for persons exposed to contagion from other diseases not infrequent escape, and even inoculations designedly made sometimes fail with u doubtedly infectious maladies. Trousseau himself firmly believed in th contagious nature of diphtheria, and at present no one doubts it.

In the 'Guy's Hospital Reports' for 1877 Dr Fagge recorded series of fifty cases of what would be regarded as diphtheria in th common acceptation of the term; and whereas eleven of fifteen cas in which the larynx was free could be brought into connection with oth cases (by either ascent or descent) only eight out of thirty-five cases which the air-passages were involved could be so brought; moreover, all th eight cases just referred to were cases in which the fauces were severe affected; of ten cases in which there were only very slight patches of fal membrane upon the tonsils or palate, there was not one in which a

ctiousness was obtained. We shall hereafter have to discuss
cts must be accounted for by supposing that when diphtheria
-passages it is less contagious than usual, or whether they
arge proportion of the cases in question belong to a different
pecific inflammation, attended with the formation of false
the chapter on Laryngitis).
f the opinion that diphtheria is highly infectious must be men-
onal fact that its contagious principle sometimes adheres with
o particular houses or apartments. Squire mentions that in a
n Scotland a visitor was attacked while occupying a chamber
had occurred eleven months before. The infection from a
enerate a severe one, or *vice versâ*.
patient ceases to be infectious is not yet known. Bristowe
ease has sometimes seemed to be communicated by a child
ntly been well for two or three weeks.
—Since the study of micro-organisms in disease by modern
een applied to infectious diseases, the whole subject of
assumed a new shape. Buhl in 1867, and Hueter and
dently in 1868, discovered in the "false membrane" of
te spherical microbes, *micrococci*, either separated or joined
n chains, or as zoogloea; mixed with these are some which
To distinguish the micrococci from mere granules of
is difficult. The bacteria present a more characteristic
ecially when arranged in long chains; but similar bodies
ce in all putrid fluids.
tes are found not only in the false membranes of diphtheria
between the epithelial cells and the leucocytes), but also in
ructures. They are described as being present from the very
of the morbid process, and as extending beyond the limits
the naked eye to separate the affected from the healthy
re said to block up the lymphatic channels, to penetrate
of muscles, cartilages, and bones, and to be carried by the
neys, where they germinate afresh. Löffler finds that the
crophyte of diphtheria (which he identifies as a bacillus, not
only present in the affected mucous membranes, not in the
idneys.
question that micrococci are really present in the tissues
d by the diphtheritic process; but it is doubtful whether
detected in the blood, and great caution is required in
n of appearances which have been held to indicate the
ganic forms in parenchymatous organs, such as the kidneys.
is important to remember that the first observations of
le, not upon cases of "diphtheria," as we define the disease,
f hospital gangrene. In other words, his facts apply rather
inflammation" in the wider sense of that term than to

nclusion probably applies to a large number of the experi-
different observers, in which animals have been inoculated
tic" products. Portions of false membrane have been
the skin, or introduced into the trachea of the dog or
he cornea of the eye has been punctured with a poisoned
ult has been a disease which proved fatal in two or three

dogs, and the tissues in the neighbourhood of the spot to which the infecti material was applied have been found full of masses of micrococci. B Recklinghausen succeeded in generating a "diphtheritic keratitis" in rabbit by inoculating the cornea with matters from a case of hospital gr grene. In Oertel's series of experiments he passed on the infection fr one animal to another, choosing sometimes the trachea, and sometimes t muscles of the neck or chest, as the seat of the induced disease; and aft six transmissions he obtained a product capable of giving rise to the formati of a false membrane in the air-passages of the last animal experimented on

Probably the constitutional disturbance caused by the so-called "dip theritic" inflammation, excited by inoculation in animals, is in many ca only a form of septicæmia; but there remains strong though not conclusi evidence that there is also a specific diphtherial micro- or strepto-coccus.

On the whole it seems probable that the rod-shaped microbes abo mentioned are only the common bacterium of putrefaction (*B. termo*), a therefore most common when warmth and moisture are combined with fi access of air as on the fauces; but that the micrococci (particularly th which occur in chains ?) are specific and pathogenic organisms. It appe that the false membranes in the larynx and trachea contain scarcely a microphytes.†

Predisposing causes.—It must be admitted that diphtheria often sprin up in isolated houses, and under circumstances which accord ill with t theory that it must be due to a specific contagion. In this there is not, deed, anything to be wondered at, for the same thing is likewise true of the exanthemata. Dr George Johnson has advocated the opinion that ca not directly traceable to infection are often due to contaminated water, or the effluvium from foul sewers or cesspools. He relates the cases of fo children who were all attacked on the same day; three days previously cesspool, distant about twenty yards from the house, had been emptied; a the wind was blowing towards the house at the time, and conveyed to i very offensive smell. Soon afterwards two of the servants fell ill, and length the mother. The only members of the household who escaped w the father (who was away from home all day) and one servant. Scarlet fev however, is also associated with bad drains and foul smells, and probal in the same way—namely, by these conditions producing a sore-throat, which the germs of scarlatina or of diphtheria alight and find a favoura nidus; or perhaps we should rather say on which they are not opposed the antagonism of healthy tissues (cf. p. 18).

There is reason to believe that, even when diphtheria is epidemic, s when the specific contagion has perhaps already been introduced into system, exposure to cold may act as an exciting cause in bringing out manifestation of the disease upon the fauces. At least Dr Yeats ('Ed. M Journ.,' 1876) states that this was the case in an epidemic which occurred Auchtergaven in Perthshire, between March and June, 1875. Several pers he says, were attacked who had been working late in their gardens,

† On this difficult subject, compare Cohn's statements as to the distinction betw *Micrococcus septicus* and *M. diphthericus* ('Beiträge zur Phys. der Pflanzen,' 2tes H pp. 164 *et seq.*). Eberth ('Zur Kenntniss bact. Mycosen,' 1872), and the 'Report of American National Board of Health for 1882' are also referred to by Klein, whose rema at p. 72 of his "Micro-organisms and Disease," and those by Crookshank in "Bacteriology" (pp. 117, 136, 177), should be read by the student.

t on a damp lawn, or driving after sunset. Others, who had
o bed for a considerable time from other causes, were infected
ppearance in the open air. It is obvious that these cases
ant bearing on the question of the existence of a membranous
rom diphtheria, since the former affection is supposed to be due
sure to cold.

ld, altogether independently of epidemic influences, can ever
ecific inflammation of the fauces, attended with the formation
rane, it is very difficult to say; it is, however, certain that
process may result from the action of more powerful irritants.
n the 'Guy's Hospital Reports' for 1877 are related the
ildren in whom the palate and tonsils presented appearances
se of diphtheria; but in one of them the affection was caused
a piece of hot potato, in the other by a burning stick, which
into the little patient's mouth by another child. A similar
een met with in three or four cases of scald of the throat, in
ater or steam had been sucked out of a teapot or kettle.
found a well-marked separable false membrane on the lingual
piglottis, as well as on the base of the tongue, in a woman who
de with white precipitate, but who lived six or seven days after
poison. There was extensive "diphtheritic inflammation"
us, the stomach, and the lower part of the intestines.

nown that, instead of attacking the throat, diphtheria some-
lf on the mucous membrane of the genital organs, or of the
enuded parts of the cutaneous surface. The study of such
isease ought to throw light on its ætiology. Dr Braxton
ded in the 'Guy's Hospital Reports' for 1871 an epidemic
n the obstetric wards, in which two women were in turn
iphtheria of the labia, while two others had the ordinary
fauces. Moreover, in Berlin and some of the other cities
any, where conjunctival diphtheria has prevailed to a remark-
re have in each epidemic been some cases in which the disease
er downwards through the lachrymal passages to the palate
n the reverse direction upwards, or in which the throat and
een attacked simultaneously and independently. Moreover,
l affection, as in a case observed by the writer, sometimes
quela of measles, just like diphtheria of the fauces. The
close a relation between these different forms of the disease
argument for its specific character, and against the supposi-
ses spontaneously, as the result of defective hygienic condi-

ne is a sporadic representative of cutaneous diphtheria.
that the conjunctival disease, even when it is of purely local
ead by contagion. If this is the fact it would be somewhat
e case of contagious porrigo of the skin, which often seems
out of simple eczema.

nd the rich are probably, in proportion to their numbers,
o diphtheria. It is notorious that the disease often carries
and robust-looking children.

Diphtheria is far more apt to attack *children* under ten years of ag than older persons; but perhaps the proportion of children appears undul large from some cases of croup being included under diphtheria.

It is doubtful whether one *season* of the year rather than another i favourable to the spread of diphtheria. Fothergill found it far mo frequent from September to December inclusive; but the very cold winter 1860 did not hinder its epidemic diffusion in London; and it has ofte prevailed during the summer. Oertel says that diphtheria is of much le frequent occurrence towards the tropics than in the temperate zone. Ge logical conditions of the soil seem to have no part in its causation.

In England it is most prevalent in London and the south-easter counties, and in North Wales; while the mortality from it is below th average in the counties north of the Humber and in the central Midlands- including the manufacturing districts of Tyneside, Lancashire, and th West Riding, Birmingham and the Black Country, and also South Wale (See Dr E. Barnes' paper, 'Brit. Med. Journal,' July 28th, 1888.)

Diphtheria as a complication of other specific fevers.—In the chapters o measles and on scarlet fever it was mentioned that each of those complain is now and then accompanied by an affection of the fauces resembling th of diphtheria. A fact related to Dr George Johnson by Dr Dewes, Coventry ('Lancet,' 1875), tends to show that both the specific contagia a present in some cases of this kind. Two brothers had been in successio attacked by scarlet fever, and had been separated from one another throug out the course of the disease. The elder had remained at his school to l nursed; the younger had been sent to a cottage in the country. The form passed through a mild form of the disease; the latter had it severely, a also had his fauces covered with diphtheritic exudation. After a time th boy at the cottage sickened with scarlet fever; and he, too, had a diphtherit throat. When both brothers had been convalescent for a fortnight th were allowed to be together, and even to lie in the same bed. Presently th elder one fell ill of diphtheria with laryngeal complications, and died on th third day.

Senator remarks that when scarlet fever is accompanied with th formation of a false membrane upon the fauces, the morbid process scarce ever extends to the air-passages.

Protection.—Does the fact that a person has had diphtheria imply su sequent immunity from the disease? In Simon's 'Report' for 1859 sever cases are recorded of individuals who suffered twice, at intervals of two three months or longer; and it is to be noted that the second attacks we always more severe than the first ones. Second attacks are not uncomm according to Dr Eustace Smith.

Incubation.—This period of diphtheria is said by Trousseau to be fro two to seven days. Oertel puts it at from two to five days; but he quot cases in which it was longer. One such instance is related by Jenner; th of a young lady who sickened eight days after having been sent into th country from a house where her brother and her sister had before be attacked. Senator says that the interval may be as much as three four weeks. Where there has been a direct transference of the poison fro one person's fauces to another's the period seems to be much shorte Valleix had a pellicular deposit on the tonsil the day after he became infect

a, and died in forty-eight hours. Oertel supposes that the
tely to be less prolonged during the prevalence of an epidemic,
the type is malignant.

nically we recognise diphtheria (the specific febrile disease
name, apart from so-called diphtheritic or necrotic inflam-
ed above, pp. 257–9) under two very different forms. In
e characters of an infective fever, epidemic in course, con-
n, with febrile albuminuria, and other "typhoid" symptoms;
auces, and the membrane is grey and causes bleeding when
e other there is less constitutional disturbance, the cases are
hough very contagious, and the affection begins in the larynx,
more fibrinous membranes.

however, combine both characters, and beginning in the
ls descend to the larynx, trachea, and bronchi. As seen in
se cases appear to be varieties of the same disease.

theria.—The course of this disease is far from constant.
gins with marked constitutional disturbance—anorexia, head-
and loss of energy; nausea or vomiting, acceleration of
vering, followed by fever. There may from the first be
llowing, the sensation varying from a slight pricking up to a
or shooting pain which may quite prevent the patient from
this pain is rarely so extreme as in acute tonsillitis. On
auces one finds that the uvula, the palate, and the posterior
rynx are more or less swollen and of a red or violet colour.
ours, or at latest two days, one or more whitish grey spots

stances the febrile disturbance is very slight, and in others
uration. The pellicles are sometimes detached and cast off,
seems to have entirely recovered within two or three days.

y cases the disease takes a less favourable course. The fever
emperature remaining at 102° or 103°, or mounting higher;
have fallen, it rises again on the fourth, fifth, or sixth day.
l spots on the fauces rapidly run together, and extend in
; so that the tonsils, the uvula, and all the visible parts of
in a few hours be covered with a yellowish or greyish
he cervical and submaxillary lymph-glands swell still more,
se at the angle of the jaw, just opposite the tonsil. Occa-
sues are infiltrated with inflammatory products, so that the
eck is obliterated, and the whole space from the chin to the
upied by a uniform brawny mass, with the skin red and
rysipelas. Before long the membrane begins to soften and
uiring a brownish colour, and separating here and there in
patient's breath then becomes horribly fœtid. An ichorous
run from the corners of the mouth, which excoriates the
ves rise to ulcers which in their turn become covered with
layer. At this time it is not uncommon for sore spots—
, for instance, or in the creases of the skin, even of remote
ody—to become distinctly diphtherial. If a blister should

unfortunately have been applied, the raw surface may be coated with a me brane; and leech-bites are apt to pass into unhealthy spreading ulcers.

From the commencement of these more serious local changes the con tutional symptoms begin to present those features of depression wh characterize the further progress of the case. The pulse may still be qui its beats rising to 120 or more in the minute, but it becomes daily smaller a weaker. The countenance rapidly acquires a waxy pallor, and the muscu power is remarkably enfeebled. Purpuric spots sometimes appear upon t skin. The tongue becomes dry and brown, sordes collect on the teeth a lips, and in fact a typhoid state may be developed. Such cases are genera fatal, and on *post-mortem* examination the serous membranes, and even t endocardium and the substance of the lungs, are commonly found to ecchymosed, as in septicæmia. Pneumonia or œdema of the lungs is, many instances, the immediate cause of death.

Occasionally there is delirium, but as a rule the mind remains perfec clear. At length the temperature falls below normal, to 97° or 96° F., a the pulse may become irregular and intermittent, its beats scarcely amount to 50 or even 40 in the minute. Death may either occur very gradually asthenia, or more often it takes place suddenly while the patient is in act of sitting up in bed or making some other slight movement. Such ca generally terminate between the tenth and the fourteenth days.

Fatal syncope, however, is not limited to those cases of diphtheria which the disease has been severe throughout its whole course; it so times happens when all the symptoms have been of the slightest. Jen relates such an instance. A boy, aged ten, who was convalescent from very mild attack, was attacked with vomiting, and the pulse (which h been becoming less frequent for two days) fell to 36 in the minute. Th was nothing in the patient's appearance to suggest that he was in immin danger, but notwithstanding the free use of stimulants the pulse contin to fall; by the next afternoon its beats were only 24, and soon af wards they ceased altogether. The following is one of two similar ca recorded by Dr Fagge. A little girl, in whom there were all along w marked diphtheritic patches in the fauces, seemed to have so little matter with her that she was allowed to play with other children in garden in front of the house. Early one morning she was being brou downstairs from the nursery as usual before being dressed, when it w noticed that she looked very pale. On being hastily sent for he found pulseless with her extremities perfectly cold, and in spite of all that co be done she died about eighteen hours afterwards, without having rallied the least from her collapsed condition.

Even when characteristic diphtheritic patches exist on the mucous me brane of the fauces, it sometimes happens that the real nature of the dise may be overlooked from the patient failing to complain of difficulty of sw lowing or pain in the throat. Children have been brought to the out-pati room at the hospital suffering from febrile symptoms for which no cause be found until, as a matter of routine, the fauces are examined. And so years ago a chlorotic girl, who had been an inmate of one of the wards a few days, died without anyone suspecting the real nature of her dise The chief symptom was a weakness so extreme that she could not sit even when supported. After death the fauces were found covered w false membrane.

But perhaps the most obscure of all the forms of diphtheria is

d to the *nasal mucous membrane*, or which, at least, may be
the presence of any obvious pellicles upon the pharyngeal
hief local symptom is then the escape of a thin sanguineous
nt fluid from the nostrils, the orifices of which become more
l and excoriated. Epistaxis is not infrequent, and it may
nat one would have attributed to it the bloodless appearance
out for the fact that anæmia is so constantly present in all
diphtheria. With a speculum we may sometimes perceive
ated bones are covered with a membranous layer, or casts of
ischarged from the nostrils. After the first day or two the
the affected parts is commonly of a brownish colour and
The disease not infrequently extends along the nasal duct
iva, which then becomes coated with a perfect diphtheritic

place, and matter be discharged through the external

rection in which diphtheria sometimes spreads is from the
he *œsophagus*. In one fatal case at Guy's Hospital we found
all ulcers in the stomach close to the cardiac orifice, some of
ted with a distinct layer of false membrane; and instances
rded in which the whole œsophageal and gastric mucous
e taken part in the morbid process. This condition seems to
to no special symptoms.

iphtheria.—The continuity of the false membranes is often
ly over the epiglottis and the aryteno-epiglottidean folds;
this is not the case, and certain observers have in conse-
d to regard the spread of the disease to the larynx and
esult of what they have termed "auto-infection," an inocula-
cous membrane by particles of secretion drawn downwards
nspired through the mouth. Upon the epiglottis and the
false membrane is firmly adherent; it may pass straight
between the true and the false cords. Below the glottis it is
ttached to the mucous surface. It becomes thinner as it
In the trachea, at a variable distance down, it commonly
omes continuous with a muco-purulent layer which lines the
assages. But in some cases even the bronchial tubes within
ent a delicate tubular diphtheritic lining. Oertel quotes
ng pointed out that this is always confined to those tubes
ards or downwards in the back parts of the lungs, and never
which course forwards towards their anterior edges. These
intain that the existence of old pleuritic adhesions over any
g favours the penetration of the fibrinous exudation into the
ronchial tubes.

n practicable to employ the laryngoscope to determine the
lse membrane in the air-passages in a case of diphtheria, and
ctised observer would be able to obtain a satisfactory view
of the larynx, at least in a child. The diagnosis of laryngeal
mainly upon the fact that the entrance of air into the lungs
This is shown not only by the rapidity and gasping character
on, but also by the way in which at each breath the soft
clavicles and sternum are sucked in, as well as the lower

intercostal spaces, and in young children even the sternum and ribs, whi at an early age are soft and yielding. Every time that the patient inspi a loud crowing or croupy noise may be audible, and the cough is often ha and brassy. In other words, the symptoms are as those of Croup, and so pathologists believe that croup, when attended with the development of me brane, is always an effect of the diphtheritic poison. The dyspnœa is apt become greatly aggravated from time to time, a circumstance probably d either to the supervention of spasm, or to the accidental impaction of portio of membranous or other secretion in the narrow chink of the glottis.

When diphtheria affects the larynx, extension of the disease to th part commonly occurs within from three to six days after the commenceme of the disease. Jenner, in 1861, had never known it delayed beyond t end of the first week; but Oertel says that it is not infrequent on the eigh or tenth day, and may be as late as the thirteenth. In Jenner's cases de always occurred in five days from the setting in of laryngeal symptom and he says that out of twenty-six fatal cases of Bretonneau's there w only five in which life was prolonged after the third day, and that th was but one in which it was prolonged after the sixth day, except as t result of operative interference.

Were it not for the circumstance that the presence of false membra in the air-passages is in itself dangerous to life, from mechanical interfere with respiration, it is probable that many cases in which the disease assum this form would be of a mild type. In other words, one need not won that the laryngeal variety of diphtheria, even when it terminates fatally, often unattended with those symptoms of bodily prostration, anæmia, a depression of the heart's action, which play so prominent a part in ma uncomplicated cases of the disease.

It is said that subpleural emphysema is of frequent occurrence fr distention and rupture of the pulmonary alveoli, and that the escaped may diffuse itself into the mediastinum and even into the subcutaneo textures of the neck and of the body generally. Bartels, in one case, hea a loud sound on auscultation, which he supposed to be due to pericardit but which proved to depend upon the presence of a quantity of air in t areolar tissue outside the heart.

In certain cases diphtheria seems to commence in the air-passag there being no primary affection of the fauces. In the epidemic form the disease, however, this is of rare occurrence. Bretonneau states that met with but two instances of it; of one of these he gives details (Case in his fourth 'Memoir'). The patient was an infant, a year old, in cha of a nurse at Tours, where no case of diphtheria had been seen for mont The nurse was a native of a hamlet some miles distant, where the dise was prevailing, and a nephew of hers had died of it a few days before t infant fell ill. Bretonneau puts the relative frequency of primary laryng diphtheria at one in thirty cases; Guersant at one in twenty cases. the epidemic which occurred at Auchtergaven (cf. p. 262), Dr Ye observed among one hundred and eighty-three cases, fifteen in whi laryngeal symptoms were present from the commencement, but in whi there was no visible affection of the fauces when they were first seen; a in six of these the pharynx remained free throughout the whole progress the disease.

In the reports made in 1859 by Greenhow and Sanderson to the Pri Council, in reference to the epidemic of diphtheria, which had been pr

e or four years in various counties of England, extension to spoken of as exceptional. Among a large number of cases alding in Lincolnshire, and recorded by Dr Capron, there are ch it was mentioned. Out of twelve fatal cases that were seen , of Highgate, nine terminated by "asthenia," three only by Birmingham it is reported that croupy symptoms were com- Mr West had never seen any marked affection of the Heslop did not think that such complications occurred in r cent. of the cases. Only at Stalham and at Smallburgh is majority of patients died with croupy symptoms, or that such very common. So, again, at Crowle, Sanderson reported o means of determining in how many cases the symptoms of ication existed; it is certain, however, that they bore a small he fatal cases. At Launceston, on the other hand, out of t appears that eighteen were preceded by symptoms of croup." ns of French physicians as to the extreme frequency of such eprived of most of their value by the very fact that these gnise no membranous croup apart from diphtheria. Breton- rs' contain forty-five cases, related in detail, and in the m the air-passages were involved. But one must remember bject of this writer was to "establish the identity of croup angina," under the common name of diphtheria; and in one rding an ordinary instance of "pharyngeal diphtheritis," he number of special cases of this kind would present no interest." ement that diphtheria extending to the air-passages is the form of the disease requires allowance to be made for the al belief on his part. For he proceeds to say that this is diphtheria takes when sporadic, and also that which it ex- es in severe epidemics. Now, the former assertion involves that sporadic membranous croup is a manifestation of Fagge found in 1877, in putting together a series of cases d croup which had occurred at Guy's Hospital, that among as would commonly be regarded as examples of the former ere thirty-five in which the air-passages were affected. But the disease may have been a non-specific laryngitis.

.—The urine is not only scanty and high-coloured, as in other but it very commonly contains a considerable quantity of fact, which was first pointed out by Dr Wade, of Birming- of great value, as sometimes aiding in the diagnosis of cases rwise be obscure. There may also be epithelial and hyaline h more rarely, blood. Eberth is quoted as having found rience albuminuria was present in two cases out of three; ion seems to vary in different epidemics. In some patients ithin a day or two from the commencement of the disease; until convalescence already seems to be established. It is transitory, and may be detected only once or twice, even in he urine is repeatedly examined; but it more often lasts o. It is generally supposed to be devoid of prognostic signifi- el, although he admits that the urine of some patients who ains very little albumen, yet says that he has been able to e relation between the quantity of this substance excreted in hours and the general intensity of the disease. From one

to three drachms was the amount usually passed in cases so severe a threaten life, or to terminate fatally; and the albuminuria persisted, those who recovered, for six or eight weeks after the subsidence of the di theritic affection of the throat.

When an opportunity is afforded of observing the state of the kidn they are said to be found large and congested, the epithelial cells be swollen, opaque, and granular, and filling the tubes. Minute extravasati of blood are also described as present in many cases; and, according to Oer masses of lymph-corpuscles often surround the capsules of the Malpighian tu The observations which have been made at Guy's Hospital would, howe suggest the belief that the affection of the kidneys differs widely in deg from scarlatinal nephritis, that observed in cases of diphtheria being comp tively of a slight character; and this accords with the well-known fact t dropsy very rarely occurs after diphtheria. A few instances of general anas have, indeed, been recorded by different observers—one, for example, Oertel in the 'Deutsches Archiv' for 1871. But when this writer speaks Ziemssen's 'Handbuch') of fifty fatal cases, mostly attended with suppres of urine and dropsy, as having occurred in Kiel and the neighbouring villa the doubt arises whether the epidemic was not really one of scarlet fe with diphtheritic complications.

It was maintained by MM. Bouchut and Labadie-Lagrave that *endocar* is of frequent occurrence in diphtheria. The author repeatedly searched such an affection in making autopsies in children who had died of the ease; but the valves have always appeared to be perfectly healthy. Sanné (who has had good opportunities of testing the value of the statem in question) declares that the slight irregularities that are commonly fo under normal conditions on the upper margins of the mitral and tricu valves have been mistaken for vegetations.

Paralysis.—Convalescence from diphtheria is sometimes attended b most remarkable sequela—*diphtherial paralysis.* This was observed by Spanish physicians in the seventeenth century. It commonly begins during second or third week after the subsidence of the throat affection, but is said be sometimes postponed until the lapse of a month or six weeks. First, the palate is affected; it hangs flaccid, the uvula cannot be drawn up; its se bility is lost, so that neither pricking it nor applying the solid nitrate of sil causes any pain. One consequence is that the patient speaks indistinctly "through his nose;" another, that when he attempts to swallow any liq part of it passes upwards and escapes through his nostrils. The pharyn muscles are occasionally involved: deglutition is then difficult, and som the food is apt to find its way into the air-passages. Next, generally afte interval of a few days, one or more of the ocular muscles may be attack the patient then sees double and squints; or paralysis of accommodation in, affecting both eyes, so that he is not able to distinguish near obj properly, and cannot read small print with comfort. The limbs are c monly affected somewhat later still, but sometimes they are the part which a loss of power is first observed. Sensations of numbness or pai the feet are complained of; and presently the legs grow weak and trem the gait is shuffling and uncertain, or the patient may be unable to st without support. The arms are much more rarely involved, but someti the patient cannot dress himself or hold anything in his fingers. He ca bend the feet on the ankles, nor extend the hands on the wrists.*

* According to Oertel, the electric sensibility and contractility of the affected mu

ances the bladder and rectum take part in the paralysis, en complete loss of sexual power in adults. Again, the larynx may be affected, in which case the vocal cords the laryngoscopic mirror to lie motionless in a position that of respiration and that of phonation—the position ys occupy in the dead body, but which is never seen under s during life. Wilks has insisted on this affection as a fre- ffocative dyspnœa, when a tracheal tube is removed, after n for a few days. The inspired current of air draws the inwards, until they meet and close the glottis. The eck and of the trunk may be affected, so that the patient is is head supported, or to raise his body from the recumbent turn over in bed. Lastly, the diaphragm or the inter- ay be paralysed, and lead to death by suffocation.

thology of this sequel of diphtheria there is still difference one extreme case Oertel says that he found extensive nal cord and its membranes; hæmorrhages surrounding the es, proliferation of nuclei in the grey matter, and fibrinous central canal. In another instance Buhl observed hæmor- nembranes and substance of the brain, and a red, swollen, the roots of the spinal nerves. See also Dr Percy Kidd's dico-Chirurgical Transactions' for 1884. The muscles have atrophied and in a state of fatty degeneration. But it is e that similar conditions are present in those cases which y in recovery. The fact that the palate is so commonly bviously favourable to the theory of a "*neuritis migrans*," a mation starting in the nerves of the part originally attacked, ong the fibres until it reaches the centres. The tenderness the affected nerves, the loss of knee-jerk, and anatomical Charcot, Vulpian, and Lépine in France, and by Leyden and any, have rendered probable the hypothesis of diphtheritic ing on peripheral neuritis (cf. Dr Buzzard's 'Harveian 85, p. 108). Senator declares that an abscess of the tonsil paralysis; and mumps is sometimes attended with a remark- of the vital functions, very like that which occurs after the other hand, some writers maintain that nervous sequelæ eria only as a member of the large group of specific fevers, s may arise after enterica, typhus, or smallpox. But this e. The only case in point that has ever come under our nat of a boy, aged five, who was admitted into Guy's Dr Wilks in the autumn of 1877 for a paralytic affection, nenced four months before, after a very mild attack of s unable to speak, and had difficulty in protruding his allowing. He could not stand, and his hands and forearms d.

The distinction between diphtheria and scarlatina, or non- is comparatively easy; the difficulty is to distinguish

d or entirely abolished, and their substance undergoes rapid wasting. denied the loss of electric contractility, and Buzzard agrees with him. action is certainly not constant. Atrophy is usually moderate, in some he muscles have a characteristic flabby feel. There is more or less ain. The knee-jerk is sometimes abolished.

between it and croup, or rather between "croup" as the result of laryn diphtheria, and "croup" from non-specific laryngitis. Both points come under consideration again in the chapters on Diseases of the Lar and on Local Affections of the Fauces.

Prognosis.—The result of diphtheria is always doubtful; no case, h ever mild, is to be regarded as free from peril. The average morta varies greatly in different epidemics, but according to Oertel it gener ranges between 30 and 40 per cent.

Age is the most important element of prognosis. The larger the portion of children among those who are attacked, the more fatal disease; for in adults it comparatively seldom assumes the fatal laryn form. However, according to Trousseau, the nasal variety is almost equ dangerous. It was observed by the Spanish physicians in the seventee century that "at its first coming it was most severe, but by degrees bec less violent—as is usual with other epidemical disorders" (Fothergill, 17

In faucial diphtheria the chief dangers are inability to swallow septicæmia; in laryngeal diphtheria, asphyxia before tracheotomy and a wards bronchitis, which more slowly but not less surely stifles the pati in both, failure of the heart.

In 70 consecutive cases of diphtheria under the writer's care (en December, 1889), the mortality was 15 in 17 under three years old, 1 33 between three and ten, 2 in 8 between ten and seventeen, and 2 in 12 in adults between twenty and fifty.

Of purely faucial cases only 5 out of 26 were fatal, of faucial laryngeal 24 out of 33, and of purely laryngeal all. In 39 cases trac tomy was performed, with 27 deaths.

Treatment.—The main indications in treatment are to maintain patient's strength, and to control the various tendencies to death. F the very first he should be strictly confined to bed. If the skin be and the pulse good, stimulants may for a time be withheld. But in m cases the heart soon begins to flag; brandy or port wine should the prescribed freely, and nourishing soups should be given in small quant at short intervals, night and day. Jenner mentions the case of a c three years old, who took from three to five ounces of brandy in twenty- hours with apparent advantage. The tincture of perchloride of iro supposed to be the best medicine. For some cases quinine, or bark ammonia, is preferred.*

As to the *local treatment* of the throat affection, there has been u tainty of opinion. All observers are now agreed that membranes upon tonsils and palate should never be forcibly removed. Bretonneau re mended that the diseased surface should be brushed over every day strong hydrochloric acid, or a mixture of one part of the acid to tw three of honey; and in 1861 Jenner expressed the opinion that powerfully corrosive agent, if once efficiently applied, would frequently the spread of the inflammation; but he advised that it should no

* Dr Hermann Weber has drawn attention to the fact that the practice, uni in England, of giving abundance of nourishment in diphtheria, is far from having ob the liability to the occurrence of the sudden collapse, which we have seen to be one o principal modes in which the disease proves fatal; but whatever may be said with r to this complication, I do not think there can be any doubt that the general tende such treatment must be good.—C. H. F.

must remember that mucous membranes with which the into contact show whitish patches for at least twenty-wards; for the writer has seen Bretonneau's practice con- day when no disease of the fauces was left, except what y the application. The white marks left by nitrate of e solid caustic or solutions in distilled water of gr. xx to so long. Liquor Ferri Perchl. Fortior has also been much ntly with local benefit.

years the practice of applying these powerful agents to the heria has been almost abandoned in all parts of Europe. come recognised that the local affection within reach is not rous part of the disease. At the present time disinfectants oyed—for the purpose of destroying the micrococci, by the parasitic theory of the disease; to lessen putrefaction surface of the affected parts, by those who reject that chlorine-water is said to be the most useful of such s accords with the results obtained experimentally by ed various disinfectants to liquids in which diphtheritic been repeatedly washed, and afterwards tested their up a putrefactive process in "Pasteur's fluid." The other h he found most effective were alcohol, solution of per-otash (gr. iss—gr. iiss ad ℥j), and solution of carbolic acid He recommends that one or other of them should be used or twice at least in every hour. Most English physicians ffering from diphtheria to suck small pieces of ice, which relief and helps deglutition.

plication on which Dr Squire lays stress is the weaker loride of iron; he adds a little glycerine to it, and paints ith a camel-hair brush two or three times a day. This acts rom the undiluted Liquor Ferri Fortior. He also recom- for a gargle, as first suggested by Küchenmeister, on account power of dissolving diphtheritic membranes. The editor has alkaloid of lecithin) locally in diphtheria of the fauces, fol- s made at Vienna :* it clears away the membrane without jury, and leaves a clear surface. Another preparation intro- hysiological laboratory is papain, from the Brazilian papaw- erful digestive agent dissolves false membrane with great have used it at Guy's Hospital, to that extent with success. ounds Oertel makes a great point of setting up a suppurative ace of the affected parts as early as possible; and he therefore vapour of boiling water should be inhaled, for a quarter of e, twice every hour, and would even reduce the patient's three or four hours, in order to keep up this treatment peaks highly of solutions of common salt and of chlorate alation. Siegel's spray apparatus is a convenient way of s to the throat, and is now much used in cases of diphtheria, ed. With very young children syringing the fauces with ime-water and milk, or with some antiseptic solution, is t efficient and least injurious procedure. Experience shows ground for the fear expressed by the elder Heberden

rkung des Neurins bei Diphtheritis," von Prof. E. Ludwig in Wien. d. Wissensch.,' 1877, No. 12).

that syringing the fauces would poison the patient by introducing pu matter into the stomach; for the danger is not in digestion, but in sorption of this matter unchanged. That admirable author concludes chapter in his 'Commentaries' which deals with the malignant sore-th (under which he probably included some cases of scarlatinal as wel of diphtheritic angina) as follows: "The gargle may be injected wi syringe into the throats of children, but this should by no means be d so often as to tease or fatigue them. Similar reasons would forbid us more strongly to take great pains in rubbing off the sloughs from t ulcers or in scarifying them. . . . . My only reason for suspec that I ought to lay more stress upon applications made immediatel the throat than I have here done, is that several physicians of deserv great authority have judged them to be of more importance than they l appeared to me." *

When the disease has its seat in the *nasal cavities*, these parts shoul frequently cleansed with disinfectants (dilute solutions of the permanga of potash or of carbolic acid, lime-water, or brine), which may be inje with a syringe every two hours, or even oftener. If the patient is enough, Weber's douche should be used. This consists of a flexible t with a nozzle fitting tightly into one nostril, through which a strea fluid is made to run by syphon-action from a vessel at a higher l The patient is directed to incline his head forwards, and to bre quickly with his mouth widely opened. The soft palate is thus draw against the wall of the pharynx, so that the fluid, instead of escaping the fauces, passes round and runs out of the opposite nostril into a basi

For diphtheria affecting the *skin*, the local application of calomel is by Trousseau to be useful; we now use iodoform. On account of liability to development of false membrane wherever blisters are appl they should never be ordered in cases of diphtheria.

When diphtheria attacks the *larynx*, an emetic of ipecacuanha or of phate of zinc should be given, and if a good result is obtained it may repeated after an interval of some hours.†

In most cases of laryngeal diphtheria the question of *tracheotomy* to be considered. Even if the air-passages can be freed from the obst tion which immediately threatens the patient's life, there is always fear that the general symptoms may increase and prove fatal; and, m over, the edges of the incision may become coated with a diphthe layer, although the mere fact that the wound looks unhealthy, and beco coated with an ash-coloured layer, is no proof that it has been expose the action of the specific poison of diphtheria. Lastly, the disease m and unhappily often does, spread below the glottis and obstruct the trac itself or the bronchial tubes.

* 'Commentaries,' chap. vii. Compare the excellent remarks by Senator on the us and mischievous attempt to apply local remedies to the fauces of young children in efficient manner.—'German Clinical Lectures,' 2nd Series, p. 447.

† Oertel recommends that a camel-hair pencil attached to a suitably curved handle sh be passed down into the larynx, and moved about so as to entangle and bring away any of false membrane that may be loose. This practice, he says, proved successful in t out of eight cases in which he employed it, the patients being respectively five, six, eleven years old. The membrane did not always come out with the instrument, but sometimes ejected afterwards by a short choking cough. He also advocates the inhalatio lime-water from a spray apparatus, but (as he remarks) very little can be expected f this procedure unless the patient spends nearly half his time over it, and most physic hold that this is too heavy a tax upon his strength.

tions for tracheotomy are rapid respiration, with laryngeal th deficient breath-sounds at the base of the lungs; pallor a purplish tinge of the lips; and sucking in with each inspi- ft parts at the root of neck and at the epigastrium, as well as os and ensiform cartilage. It is better not to delay the opera- ting has failed to relieve.

heotomy it is probably best to abstain from all treatment g the tube and removing membrane and muco-pus from the soft feather. Children under a year old generally die; the f the trachea, the yielding nature of the chest walls, and the eding them are the causes of this high mortality. When a o swallow, liquid food must be poured down one nostril is closed, not through a catheter, but by a funnel inserted . Nutrient enemata are rarely successful for more than a children. Brandy in frequent doses is of great service.

ied intubation instead of opening the trachea, but so far the t been encouraging.

ers.—After death from diphtheria, the lungs are found in *collapsed* in several lobules; and in all cases the tubes are and mucus. Ammonia and senega, sweetened with treacle u, is the best medicine, and brandy the best form of stimu- h to prevent this condition.

nger is *failure of the heart.* A boy of eight or nine under re went well through a severe attack of diphtheria, then plegia, and died suddenly from syncope; we found acute he heart, as after some cases of scarlet fever. Steel and digitalis are probably the best means of preventing this catas- ion to food and alcohol. Feebleness of the pulse and the first art resembling the second are indications of the danger.

tients may die from *septicæmia*, and this must be met by local ntiseptics, and by such remedies as quinine and alcohol.

is very rarely fatal; if so, it is from a branch of the external bly from the trunk of the internal carotid artery.

f sequelæ.—Diphtheritic paralysis is the most important of rally subsides spontaneously within three or four months, and h earlier. A case under Donders in which recovery did not ten months had elapsed is exceptional. Some years ago, how- he to Guy's Hospital as an out-patient who had been in our rs previously for this affection; he was still unable to swallow fluids sometimes returned through his nose if he tried to This paralysis is very rarely fatal; but sometimes the patient ntly with slightly impaired power of certain muscles.

cated in cases of this kind, and often seems to be very useful. o the administration of nux vomica or strychnia, and he does that galvanism or faradisation should be employed, except at a

SYPHILIS*

"Consumptions sow
In hollow bones of man, strike their sharp shins,
And mar men's spurring. Crack the lawyer's voice,
That he may never more false title plead,
Nor sound his quillets shrilly: hoar the flamen,
That scolds against the quality of flesh,
And not believes himself: down with the nose,
Down with it flat, take the bridge quite away
Of him that his particular to foresee,
Smells from the general weal: make curled-pate ruffians bald."

Congenital syphilis—Its transmission to the child—Syphilitic placenta—Lo manifestations—Its further transmission—Its treatment—Later effects.

THE disease which was first recognised about three hundred years a and received the name of Syphilis, was then regarded as a pestilen an epidemic disorder—spreading like the plague, or putrid fevers, by conditions of the air, and conveyed by infection at a distance. After time it was discovered to be closely connected with foul local disorders the genitals, and to be as a rule communicable by sexual congress. In t seventeenth and eighteenth centuries syphilis was generally known as t venereal disease (*lues venerea*), and was supposed to spring from any form local disease acquired in impure connection. Its constitutional effects w until lately compared with those of Gout and of Tubercle, and thus syphilitic "diathesis" was placed side by side with assumed "arthriti "scrofulous" and "malignant" diatheses. Inherited syphilis was unrec nised after infancy, or was confounded with what was called "scrofula;" a "scrofula" itself was often supposed to be the expression of a dist syphilitic taint. Owing to the labours of Ricord, Bassereau, Hutchins and many other observers, the accidental connection of this disease w others of venereal origin no longer obscures its distinctive characte it is completely separated from tuberculosis both in its acquired and hereditary forms, and it now resumes its original place among specific co tagious diseases, as not always venereal in origin, and not more different fr typhus, measles, or smallpox, than are diphtheria, erysipelas, and cholera.

* *Synonyms*—Lues venerea—Lues—Morbus gallicus—The pocks or great pox.—*Fr.* grosse vérole, *Germ.* Lustseuche.

either the writings of antiquity, nor those of the Middle descriptions of syphilis. What first drew attention to this epidemic prevalence in Italy at the end of the fifteenth Charles VIII of France invaded and occupied Naples. It sed to be a new malady; either generated by the filth of a trange wickedness of mercenary troops, or introduced from overed Western World by the sailors of Columbus, who pe about the time when it broke out. However, there are belief that the disease had been observed in France, in n Italy, as well as Spain, before the expedition of Charles), and when Columbus had not yet reached the port of Palos or at least had only recently landed his men there on his first voyage to the West Indies. Critical inquiries seem to probability syphilitic affections were by no means unknown s centuries, although they were confounded with other ularly with leprosy.

epidemic of 1494 and the subsequent years was unusually ancereaux supposes that almost a twentieth part of the attacked, and although few died, fewer still were cured. n lost its pestilential character, and by the middle of the ry its type resembled that with which we are now familiar. , its diffusion was at first ascribed to climatic influences, in real mode of conveyance.

demics of syphilis have since been observed, which have entirely misunderstood, and described under a variety of ne affections, long regarded as peculiar to certain regions, tly been recognised as syphilitic. A disease which attacked d eighty persons at Brünn, in Moravia, in 1578, one which a in 1780, and the "Scherlievo" of Fiume at the beginning were almost certainly local epidemics of syphilis; and s was called "the Sibbens" in the West of Scotland, " in Norway.

ent time the disease is found in almost every part of the different degrees of frequency, according as the conditions r otherwise for its usual mode of propagation. Among the celand it is said never to have established itself, although it been introduced by sailors; according to Livingstone, in the blood in the centre of Southern Africa it is mild and effects; and in China and Japan it seems to be seldom eaux cites French physicians, who had studied it in these have suggested that its virulence has gradually become ts wide diffusion through the closely packed population nerations. Upon the same authority it is stated to acquire ate degree of intensity when it passes from a Chinese Similar assertions have been made with regard to its m one race to another elsewhere,—in the case, for in- British army in Portugal during the Peninsular war. Its ear in seaport towns, where vice and intemperance prevail

e term "Syphilis" was invented by Fracastorius, a learned rona, who in 1521 published a poem under that title, in d how *Syphilus*, a shepherd, was stricken by Apollo with

the new disease—even then not recognised as venereal.* It is a great pi
that we have not for every specific disorder a name as distinguishing,
short and flexible, and as free from meaning.

The French early contrasted *la petite* with *la grosse vérole* (i. e. *variol*
just as in England the word "smallpox" formerly conveyed a similar d
tinction.† Many other names, employed in various countries, indicated
belief that the disease was of foreign origin. Thus, while it was *mal*
Naples to the French, it was to the Italians *mal francese*;‡ and, unhappi
the Sandwich Islanders first knew it as the "English disease." At o
time the most common designation was *lues venerea*, which dates back
Fernelius (1556). But the venereal disorder was held to include both gon
rhœa, proved to be distinct by Ricord in 1831, and the soft chancre, wh
nearly all pathologists now regard as an independent affection. Inde
the conception of syphilis as a general malady, comparable with the ex
themata, had no existence until about forty years ago. It is true that Jo
Hunter described a constitutional form of the venereal disease, but
expressly taught that the action of the poison on the blood was differe
from that which occurred in any kind of fever. Since the modern vi
has been accepted the name of Syphilis has superseded most others, b
Lues and its adjective "luetic" are still used abroad.

Pathology.—Like other results of purely scientific and speculative inqui
the recognition of the true nature of the disease has proved of the utm
practical importance. The physician must almost forget the local prim
disease and put aside the idea that the diagnosis of syphilis carries wit
the stigma of impurity. There are many ways in which a person may
a victim to syphilis without illicit intercourse; and in exceptional instan
one must be prepared to recognise its manifold varieties in patients
either sex, at any age, and in every position of life.

In the second edition of this book Syphilis was accordingly inclu
among the specific febrile diseases. It arises by contagion alone,
breeds true; inoculation is followed by a latent period of incubation;
onset is febrile, with an exanthem and a local lesion in the throat; lastly
has definite sequelæ, and protects against a second attack.

The contagium has not yet been certainly identified. Lustgarten
discovered that a bacillus, resembling those of tubercle, lupus and lepr
occurs in the cells of the diseased tissue.§

The chief peculiarities of Syphilis are the slightness of the pyrexia,
slow evolution of its stages, the importance and frequency of its sequelæ,

* The *locus classicus* is as follows:— " . . . . primus
Syphilus ostendit turpes per corpus achores:
Insomnes primus noctes convulsaque membra
Sensit, et a primo traxit cognomina morbus
*Syphilidem*que ab eo labem dixere coloni."
—HIERON. FRACASTORII, Veronensis, Syphilidis sive de Morbo Gallico lib. iii, v, 3

† My learned friend, Dr Norman Moore, informs me that the term "pocks" freq
occurs in Irish and other mediæval MSS., and probably refers to cutaneous syphilis.

‡ It was called the French disease also in England:—
"News have I that my Nell is dead i' the spital
Of malady of France."—*K. Henry V*, v, 1.
The passage from 'Timon of Athens' (iv, 3), which stands at the head of this ch
shows how familiar the symptoms of secondary syphilis had become by the beginning o
seventeenth century.

§ 'Med. Jahrb. der k. k. Ges. der Aerzte,' 1885. See also 'Brit. Med. Journ.,' Oct.
of the same year, p. 757.

mission, and, we may add, its reaction to remedies. As
g hereditary, Mr Hutchinson well argues, that smallpox and
e, like syphilis, occasionally transmitted from mother to
revity and severity of these and other specific fevers make
ible for them to be imparted by inheritance.

disease.—Incubation—When a person is affected with the
here elapses, in uncomplicated cases, a considerable interval
ny symptom is observed. This is the period of incubation.
kable that this fact was unknown until, between 1856 and
xperimenters inoculated syphilis upon healthy individuals.
ler, in 'Ziemssen's Handbuch,' brings together thirty-one
his kind, in the very large majority of which the incubation
n to twenty-five days. Once it was only ten days; four
hirty-five and forty-four days. In 1865 Fournier recorded
in which no treatment was adopted, so that the disorder
naturally. The incubation was more often over than under
not infrequently reached a month or six weeks, and once
o ten weeks. In one patient of Bäumler's, in whom the
posure to the poison was known, the incubation was twenty-
ther twenty-nine days. Frequently incubation is prolonged
more. The idea that no such period occurred was based
atural tendency to ascribe the disease to the last impure
eding its appearance, partly upon the circumstance that
at of the soft chancre), which produces an effect almost at
nsmitted in association with that of syphilis proper, and
recognised as distinct.

.—The earliest symptom of syphilis is manifested at the
it is spoken of as the *primary* lesion, while the most remote
appear elsewhere are termed *secondary*. It is often called
ian "chancre," but upon the skin its typical character is that
d papule. This, which is at first very small, soon increases
grows larger becomes indurated, so that to the touch it
ce of cartilage let into the part. After a week or ten
quamate slightly; or a little moisture may ooze from its
ently dry up into a thin scab; or it may continue to look
zed; or, lastly, it may become excoriated, and slightly
centre. Upon a mucous membrane, the primary affection
s a very small itching vesicle with a reddened base, which
ning an erosion, and afterwards a shallow ulcer; this, too,
rated floor as it enlarges.

of these lesions has been investigated by several observers.
d an abundant infiltration of nucleated cells, not only
lles of connective tissue in the cutis or mucous membrane,
dventitia of the blood-vessels, which are thereby narrowed.
s that there is an actual development of connective-tissue
he periphery of the indurated mass, and that this is the
ness, which by Auspitz had been attributed to the presence
dation between the cells and the spaces in which they lie.
f the primary lesion of syphilis varies in different cases.
ses quickly away, leaving no trace of its presence; but when
it generally takes many months in subsiding, and upon the

skin its site remains marked by a brown pigmented patch, with more or superficial scarring in its centre. On the other hand, mucous membra never show pigmentation, and all that is left by even the largest papule i little vascularity and looseness of texture. Mr Hutchinson has dra attention to the fact that in some individuals an induration, like cartil appears again and again during a period of several years exactly whe former primary syphilitic lesion was situated, without any fresh infecti Ultimately even the pigment disappears, and it may then be quite impos to discover that the patient has ever suffered from primary syphilis.

Hard and soft sores.—The typical primary syphilitic lesion is still o called a Hunterian or indurated chancre; but if (as is often the case) it the characters of a chancre, or "sore," they are accidentally present ra than essential. Bäumler calls the primary lesion of syphilis, not a chan but an "ulcerating sclerosis."

In 1852 Bassereau took the pains to trace to their origin in the oppo sex a number of venereal cases; and this method of "confrontation" (a terms it) showed that, whereas sores which were followed by second symptoms had been derived from persons who themselves suffered un similar effects, other sores which remained simply local, or which at n were attended with suppurating buboes, came from individuals in whom disease had likewise failed to produce any constitutional effects. His vi were soon afterwards adopted by Ricord, who indicated a number of dist tions between the two kinds of lesions in question, of which one bec known as the "indurated," "Hunterian," or "infecting" chancre, and other as the "soft" or "non-infecting" chancre. His account of the infec chancre need not be quoted in this place, except to mention the import fact, which was now brought out for the first time: that the ordin slight secretion of such a sore cannot be inoculated upon the pati nor upon anyone else who has already had syphilis. Bidenkap indeed, since found that there are occasional exceptions, it being so times "auto-inoculable" during an early stage of the disease, when th have as yet been no constitutional symptoms. But such observations dently do not affect the principle on which the rule is explained, since t are strictly parallel with the fact that vaccination can be successfully formed before the eruption of smallpox appears, *i. e.* before the infection become generalised throughout the body.

Ricord's description of the non-infecting chancre was that it beg (without any incubation) in a pustule, which in two or three days brea that there is then formed a deep, punched-out ulcer, with irregular slightly undermined edges, a grey surface, and a soft, or at least not indurated, base; that it secretes pus freely, and that this is inoculable ag and again upon the same individual, and also upon all other persons, whet affected with syphilis or not. One consequence of the difference in inoculability of the two affections is that whereas there is seldom more t one indurated chancre, several soft chancres are often seen together. soft chancre is scarcely ever seen except on the genital organs. histology of the soft sore is not so different as might have been expe from that of the primary lesion of syphilis. There is a similar infiltrat of cells into all the tissues, including the walls of the blood-vessels, but i said that the channels of these vessels are dilated, instead of being narrow The cicatrices left by non-infecting chancres are often irregular in form, much more conspicuous than that which follows a typical Hunterian sore.

not appear to be any doubt as to the correctness of Basse-
ons, nor as to the general validity of Ricord's distinctions
kinds of venereal sore. But subsequent experience has shown
al application of those distinctions in the prognosis of such
le to certain sources of error. And the theoretical question
der discussion, whether the poison of the soft chancre is or
gin independent of syphilis. It is hardly necessary now to
nfusion which at first prevailed in consequence of the way
l and those who followed him formulated their doctrines.
king of the "duality" or "unity" of the chancre, they in-
uality of the syphilitic virus. Thus they drove from their camp
egarded syphilis as a single specific disease, comparable with
fevers, while yet there was no place for the dissentients
opponents, who advocated the *unity* of the local soft sore
is followed by constitutional symptoms. This, however is
han a verbal difficulty.

onsiderations bearing upon the theoretical question as to the
ontagious principle of the soft chancre are the following :—
net with a case in which an indurated chancre on the scrotum,
ondary symptoms, had inoculated itself upon the skin of the
h it came into contact, producing there a sore which remained
ation. Another patient under his observation had an indu-
he grey surface of which suggested that its secretion would
the experiment was tried on the patient himself, and the
t sore which reached the size of a franc-piece. It is evident
are easily explicable on Rollet's theory, that "mixed sores,"
the virus of syphilis and the contagion of the soft chancre,
non. But the view which Clerc adopted was that the soft
ing else than the product of inoculation from an infecting
person who is suffering or has suffered from constitutional
as if there were not already sufficient confusion, he proposed
se of the term chancre to the indurated primary lesion of
call the soft sore a "chancroid." Shortly afterwards Mr
wed that an indurated sore, when irritated by savine oint-
red savine, could be made to pour out a purulent fluid which,
l upon the bearer or upon other patients, produced, without
a sore having the characters of a soft sore, and capable of
d again and again. And lastly, Pick, of Prague, found that
e of scabies, or pemphigus, or acne, was also capable when
syphilitic subjects, of generating a similar soft sore, although
t healthy individuals in the same way. From these experi-
ypothesis derives far more support than from his own observa-
he alternative theory of Rollet can be altogether set aside.
ne case that the sores obtained by Lee and Pick are identical
res, one may be justified in concluding that such chancres are
-product of syphilis, and that their contagious principle is
vo in persons suffering under that disease. There is reason
in mucous patches (or flat condylomata), themselves due
re often arises a virus which is capable of transmitting them,
of all other symptoms of syphilis, to healthy individuals.
irly comparable with those which seem to show that in various
f the human body animal poisons may be developed which

may set up erysipelas, or even perhaps diphtheria, in other patients; bu we, with Mr Hutchinson, speak of soft chancres as "abortive inoculatio the difficulty remains of explaining how their contagion possesses a virule of a certain kind which is wanting in the secretion of a true infect chancre. That it is not a mere question of the presence or absence pus is shown by Ricord's observation, that the matter from the inte of a suppurating gland produces a soft sore when inoculated, whe this is not the case with the matter which is formed in the connect tissue outside it.

From a practical point of view, however, the origin of the soft chan is of minor importance in comparison with the question whether it conta the virus of syphilis: that is, whether it remains local and can only pro gate itself, or whether it is liable to be followed by constitutional sympto In principle the first of these statements appears to be correct, but unfo nately it is open to exceptions, which interfere with its application in prognosis of individual cases. If we accept the theory of "mixed chancr promulgated by Rollet, of Lyons, in 1858, it follows that, if a perso infected at the same time with the poisons of the soft chancre and syphilis the necessary result must be the immediate production of w appears to be nothing but a soft chancre, which will not assume an indura character until the lapse of three or four weeks, corresponding with incubation of syphilis. Such sores are believed to constitute an act majority of the primary syphilitic lesions which are seen in the hospitals large cities. It is, however, a question whether the rapid spreading of base and sides of a soft sore, which sometimes occurs, may not lead to destruction of any syphilitic poison that may be present in it, and thus s the patient from further ill-effects. In this way it may be possible account for an occasional failure in the transmission of syphilis from a per suffering under that disease to one who has never had it, notwithstandi the occurrence of a chancre in the latter. Bäumler states that there only seven experiments on record in which the artificial inoculation unquestionably syphilitic secretions upon healthy persons has not commu cated the constitutional affection. On the other hand, it not unfrequen happens that a male patient derives syphilis from a woman in whom a s sore is the only discoverable primary lesion; and the best observers h been obliged to allow that they have seen instances in which a sore t has at no period been indurated was followed in the same individual secondary symptoms. Mr Morgan, of Dublin, has especially insisted the fact that in the Lock Hospital of that city he scarcely ever saw indura chancres in the very class of women from whom the men who come to institution derived their venereal disease. But this proves less than mi at first sight appear, now that we know that the secretions of moist second eruptions contain the specific virus: and Mr Cooper Forster stated t at Guy's Hospital he generally succeeded in finding a characteristic prim affection in female patients when he carefully looked for it.*

* All difficulties in the matter are sometimes explained away by saying that the ind tion is occasionally very slight and parchment-like (*parcheminée*), so that it can be dete only by taking the sore between the finger and thumb in a particular manner, whic impracticable in the case of a female with a sore situated within the vaginal orifice. this is in reality equivalent to the admission that the primary lesion of syphilis does invariably present the distinctive characters which are assigned to it. Conversely, typical induration is sometimes closely simulated by inflammatory thickening of the flo a soft chancre as the result of irritation by caustics.

practice, although it is easy to say that certain "hard" sores are sure to be followed by secondary symptoms, it is seldom, if ever, e to assert that any sore, however "soft," will *not* be so followed. It consequently be unadvisable to attempt to limit the use of the term ere" to sores from which the syphilitic virus is absent, as has been ed by some writers, including Mr Forster. We had much better keep riginal meaning, and apply it to all *ulcers*, whether syphilitic or not, are directly due to venereal infection.

nstitutional symptoms of syphilis are sometimes seen in persons in no primary affection is known to have occurred. One source of in these cases is that a primary lesion sometimes assumes the appear- a secondary one. Thus, a parchment-like glazed papule on the glans nay be undistinguishable amid a general papular eruption, while on bium the affection may be so modified as to simulate a "broad oma" or "mucous tubercle." In other instances, perhaps, it is so picuous that the patient never notices its presence, and it quickly s, leaving no mark. But some observers admit cases of true "*syphilis* ," *i. e.* the invasion of the general malady without a local lesion.

-exanthemic period.—The primary, or latent, stage of syphilis is cha- ed by swelling and induration of those *lymphatic glands* which bear an ical relation to the seat of the primary chancre or papule. So constant ymptom that Fournier failed to detect it in only three out of 265 cases , and in the same number among 223 cases in women. The glands correspond with the genital organs are, of course, those in the groins. urated sore upon the finger leads to enlargement of glands in the or at the bend of the elbow, particularly of the small lymph-gland lies just above the internal condyle. One upon the lip affects those e lower jaw. These "amygdaloid" glands reach the size of almonds, be a little more, but they never approach the dimensions of the ating bubo which accompanies a soft chancre. They feel hard, ely moveable, and are seldom tender or painful. There is generally dening of the skin over them, and they scarcely ever suppurate. mes along the dorsum of the penis an inflamed lymphatic vessel can like a cord.

is "indolent bubo" of syphilis, as it is termed, appears a few days han the primary lesion. A chain of glands is commonly affected, ten those in both groins at the same time. The swelling runs an ingly slow course, so that it often does not begin to subside until six s have elapsed. Thus it may be very useful in diagnosis, by indicat- e probable seat of a chancre or papule, the marks of which might ise have been overlooked. One must, however, remember that s is not the only cause of a similar affection of the inguinal glands; oper Forster insisted on the frequency of the occurrence in rowing nd it may also be seen in young men accustomed to much walking. in other regions are liable to become enlarged apart from syphilis, and gh the firm, painless, separate bullet-glands are usually characteristic, ay occasionally feel something very similar in cases of irritative ement, and in Hodgkin's disease.

e appearance of the primary papule or chancre of syphilis is followed interval during which we may suppose that the virus is undergoing lication in it and in the adjacent glands. The lesion itself now and ubsides in the meantime, and so the period is sometimes spoken of as

a second incubation, or latent period. Its length is generally si *seven weeks;* but it is liable to wide variations, as is shown by the that where the disease has been inoculated experimentally it has found to range from twelve days to twenty weeks. Probably it is sh in persons who are weakly, or whose habits are dissolute or in perate, than in those whose general health is good. During its co some patients look and feel well; but others—it is said, particul women—complain of malaise and depression, and have a pale and hag aspect.

Secondary stage.—The general or *constitutional* symptoms of syp begin differently in different cases. In some there is well-marked fe the temperature rising suddenly, or gradually, until within a few day may reach 104°. With the appearance of an eruption it sometimes decl but it may run on for several weeks, assuming, as Bäumler has shown intermittent type resembling that due to malaria. The proportion of c attended with febrile disturbance is stated by Güntz at 20 per cent.; Bäumler thinks that it is really higher.

A more frequently noticed and very characteristic symptom of period is what French writers term *bitemporal neuralgia;* the occurren more or less violent pains, which shoot upwards along each temple. T are not felt at all periods of the day, but come on, often with surpri regularity, in the evening or at night. A similar tendency to noctu exacerbations, indeed, belongs to all other painful syphilitic affecti Ricord used to ascribe it to the warmth of the bed, and said that in per whose occupations compelled them to sleep during the day, the tim which the pains returned was reversed. But, whether or not this is fact, there can be no doubt that his explanation of it is incorrect. For hour at which the bitemporal neuralgia sets in is often early in the even while the patient is still up; and Bäumler is probably right in thin that it coincides with an increase of fever, and is in some way depen upon augmented vascular excitement. Pains in the back and limbs ma present, and there may even be swelling of the joints. The writer has se distinct, though slight and painless, enlargement of some of the artic tions of the fingers; and Bäumler speaks of patients seeking advice for and swelling of the metacarpo-phalangeal joint of the thumb, but leavin to the physician to discover that they have syphilis.

Syphilis of the skin.—Unlike all other specific poisons, the virus of syp produces not merely one or two definite cutaneous affections, but an imm variety. They are known as *syphilides* or collectively as syphiloderma (n properly syphilodermia); they shade off into one another so as almos defy description, and are classified with the greatest difficulty. W regard to the causes which lead to the evolution of one of these erupti rather than another, all that we at present know is that a patient who i a bad state of health is most likely to have those forms which suppu and ulcerate. The differences between them are by no means attribut to tendencies towards particular non-syphilitic cutaneous diseases; instance, a person liable to ordinary psoriasis is not specially apt to affected with a squamous syphilide, nor one who has lichen with a pap one. We should, therefore, avoid using such names as "syphilitic lich "syphilitic ecthyma," or "syphilitic psoriasis." However difficult diagnosis may occasionally be in individual cases, syphilitic affections

y distinct from the non-syphilitic eruptions which may simulate them, hology, in prognosis, and in treatment; and therefore, since a name hould indicate a diagnosis, the terms psoriasis and roseola alone become , if liable to be contradicted by the far more important qualification litic." A non-syphilitic disease, as psoriasis, is not more "modified" hilis, than is scabies or a typhus rash; any of the three may be seen incidence accompanying cutaneous syphilis, but unaffected by it.

ere are certain features which belong, more or less, to all the des. (1) One of them is a peculiar colour, which is commonly said to le raw ham, or to be "coppery:" according to Bäumler, the former rison has been traced to Fallopius, who wrote about three hundred go; the latter only to Swediaur, at the commencement of the present y. The cause of the tint is probably a chemical change in disintegrat- od-discs which have been extravasated into the tissues, and therefore t present at first; while, on the other hand, a very similar appearance times displayed by non-specific eruptions, of chronic course, especially legs, where the venous circulation is apt to be embarrassed. (2) A character of syphilitic cutaneous affections is their multiplicity or norphism" in the same patient and at the same time. Sometimes s, papules, pustules, scaly patches, are so intermingled that we cannot ich of them preponderates. (3) A third point, which is, however, not r to the syphilides, is their tendency to arrange themselves in circles or cles, or less completely annular forms. (4) Unless their development rapid, they are seldom attended with itching; in many cases the experiences nothing whatever to draw his attention to the skin. (5) rliest rash, or any universal syphilitic eruption, may be symmetrical, the exanthem of measles or smallpox is symmetrical, because it affects nmetrical human body. But syphilides do not show the characteristic try of psoriasis, eczema, and some other cutaneous diseases, in picking rresponding parts of the trunk or limbs. They are irregular in distri- . Their favourite localities are the forehead, the soles of the feet, and ms of the hands, and they often affect regions rarely visited by other ous affections.

important distinction has been drawn between the earlier and more cial syphilides, and those which are later in appearance, and affect the t layers of the skin. The former, to which some writers limit the *econdary*, may relapse several times, but their first appearance is very postponed beyond twelve months from the time of infection. The which are often called *tertiary*, seldom appear within the first year, ey may break out for the first time after an interval of many years. listinction of time is not, however, constant. "Tertiary" lesions e occasionally seen very early, but the more superficial secondary des seldom appear very late, and probably never after tertiary forms ecome developed.

thologically, the roseolous and other secondary eruptions may be com- to the exanthems of variola and typhus, while the tertiary syphilides less complete counterpart in the suppurations which occur as sequelæ asles and enteric fever, or perhaps they may be more justly compared secondary growths which follow a malignant tumour.

art from the period of their development, secondary syphilides are mperfectly symmetrical; tertiary almost always avoid even an approach teral symmetry. The secondary rashes commonly consist of numerous

isolated spots or patches. They seldom affect the hands or feet, are paratively superficial, have little tendency to ulcerate, and leave no cica behind them. On the other hand, the so-called tertiary dermatos syphilis consist of comparatively few separate lesions, but they gen run together; they affect the deeper layers of the integument; they de the tissues, and are followed by scars. These distinctions are not abs nor do they apply equally to every form of syphilide belonging to the or to the late group, but the exceptions are few.

The special character of the several syphilides will be most usefull cussed along with other diseases of the skin from which it is of the u importance to distinguish them, but the following brief account has re to them as parts of the pathological evolution of the general specific di

1. *The macular or exanthemic syphilide* ("syphilitic roseola") is earliest and most constant of all, and answers to the exanthem of m and scarlatina, or perhaps more closely still to the occasional early rose of smallpox. It consists of rather ill-defined, pale or dark, rose or "cop coloured spots, irregular in form, of small size, or approaching that threepenny piece, or even larger; scarcely if at all raised above the su and generally disappearing under pressure.

This is most constantly seen upon the chest and abdomen, but some it covers most of the trunk, and appears on the neck and face; o limbs it is less common, and it avoids the hands and feet. As a ru takes a week or more in coming fully out, but sometimes it is develop rapidly that the case may be mistaken for one of measles. A pal scanty eruption often fades within a fortnight. One which is dark col and abundant may remain visible for several weeks. It may then assu papular form or disappear with slight desquamation even when no ment has been adopted.

2. *The papular syphilide* ("lenticular syphilitic lichen") is the common form to follow the initial rash. It consists of red shining tions often of a marked coppery tinge. In size they vary consider some being scarcely bigger than millet seeds, others as large as peas. develop themselves very rapidly, reaching their full magnitude in a few They do not, however, generally all come out at once, but rather in succe crops over a long period.

The eruption is sometimes scattered irregularly over the whole b sometimes the papules are grouped together in clusters. They are times most numerous on the neck and forehead; sometimes they are th crowded in the naso-labial grooves, or at the angles of the mouth. generally remain for some weeks and then subside, leaving dark st but not unfrequently they desquamate, so as to pass into a squa syphilide, or their summits soften down and become covered with y or brown crusts.

In consequence of the thickness of the cuticle of the palms and these parts show, not raised papules, but flat round horny plates, each a reddish-brown border. After a time the plates become detached, for so many little ulcers, or the adjacent surface becomes rough and and cracks or fissures may be formed. Thus a complicated affe arises, constituting what used to be called "syphilitic palmar and pl psoriasis." This form is the most constantly symmetrical of all syphilides.

3. *Mucous patches.*—Another modification of the papular syphilide is

rts of the skin which are thin, and habitually in contact with other and also upon mucous membranes. The lesion is known as a ous tubercle" or patch—"*plaque muqueuse*,"—a 'flat, broad, or moist *loma latum*," so called to distinguish it from the "pointed condy- (*C. acuminatum*) or "wart" of the genital organs, which is often yphilitic in origin.

consists of one or more broad raised patches, from the size of a to a half-crown, with a sharply defined edge, and a surface which is imes dry and warty-looking, but usually moist and coated with a dirty secretion, of a peculiarly nauseous, pungent odour.

ucous patches occur, sometimes in large numbers, about the genitalia, lso along the perinæum and round the anus, in the fold of the in the groins, at the umbilicus, at the folds of the axillæ, beneath easts, in the neck, between the toes, at the angles of the mouth, and here. Not infrequently they are so placed upon opposed parts of the s strongly to suggest the idea that they spread by local infection. If s the case it is one of great theoretical interest, since a patient who y has syphilis is believed to be absolutely protected from the further nce of the virus, so that flat condylomata would possess an independ- ontagion peculiar to themselves. They may certainly be the means ich syphilis is transmitted to other persons. In such cases they gene- give rise to a typical primary indurated papule, which is followed after ual interval by constitutional symptoms; but it is equally certain that he cases the affection which they set up in non-syphilitic individuals is inguishable from a flat condyloma, and cannot be proved to contain philitic virus. This is admitted by Kaposi, but he passes it lightly by he remark that secondary symptoms sometimes fail to appear, even n indurated primary sore. Yet so common is the occurrence of flat lomata, apart from all other indications of syphilis, that careful ers have in some cases attributed them to mere irritation of the e by dirt and moist secretions. Moreover, in some countries they been known to prevail endemically in such a way that their connection yphilis has been altogether a matter of inference. These considera- seem to point to the conclusion that, although the affection owes its to syphilis, it yet acquires a contagious principle of its own, which is le of surviving and reproducing itself by contagion after the original itic virus has in some way disappeared or become exhausted; if so, ends strongly to corroborate the doctrine that the soft chancre arises preads in a similar manner.

The squamous syphilide ("syphilitic lepra or psoriasis").—Contrary to once was taught, this, as an independent eruption, is infrequent. We seen that the macules and papules of syphilis often after a time e scaly. If such spots go on spreading still further, there arises fection which may resemble psoriasis; but it is distinguished by nall and scanty scales, the copper-like tint of the patches, and the ce of the definite and symmetrical distribution so characteristic of sis.

The pustular syphilide ("syphilitic ecthyma and rupia").—This is a collection of several different varieties of eruption than a single well- cterised form. It consists of pustules of all sizes, each of which is ally seated upon a firm red base. They are sometimes present in nse numbers, especially upon the face and trunk. They come out

rapidly and sometimes with febrile disturbance, but in successive c which may be prolonged over many weeks; and they may relapse after a year has passed. They dry up into brown, or dark green, or b scabs, and leave large stains, which ultimately pass into shallow, flat, w cicatrices.

Concomitant early affections.—One of the points in which syphilis resem some of the acute exanthemata is its strong tendency to affect the *fauc* well as the skin. Indeed, the throat sometimes suffers before any cutan eruption can be discovered; and in other instances an inspection c reveals morbid changes, which had caused neither pain nor discomfor that the patient had no suspicion of their presence. The acute angin early syphilis appears as a diffused redness, and not in the form of dis maculæ, contrasting in this respect with the sore-throat of measles. T is often much swelling, particularly of the tonsils. The follicles be enlarged and prominent; or they may rupture, and cause shallow excoriat In more chronic cases flat, greyish mucous patches are seen on the tonsi the palatine arches; or there may be yellow ulcers, with sharply defined borders. The most curious affection is one which is seen not only upon fauces, but also upon the hard palate, the inside of the cheeks, and the It consists of scattered milk-white spots, which have been termed *pl opalines*, and which are perhaps best compared with those caused by ap ing nitrate of silver to a mucous membrane. Their shape may be ro oval, or indefinite; they vary in size, and may run together so as to co large surface with an irregular pattern. Sometimes they are slig puckered, and parts of their surface may be reddened, with only a white opacity here and there. All their varieties are deserving of ca study, for they are very characteristic of syphilis. They run an exceedi slow course, and may break out again and again, not only during the stage, but also long afterwards.

In many cases the *eyes* suffer. The affection most commonly observ an iritis, attended with the formation of yellowish-red nodules near edge of the pupil. This is generally bilateral. In Hutchinson's experi it arises within the first six months of the disease, if at all. It is gene associated with one of the more severe forms of eruption. Later attack said to be always relapses; they are often limited to one eye at a time. retinitis may occur, in which case the fundus of the eye has a hazy app ance when seen with the ophthalmoscope; the disc is reddened and swo and its margin is indistinct; there may be many small extravasations of bl The recognition of this marked change is very important, because o insidiousness; Hutchinson speaks of the patient as noticing "nothing ex that his sight is very dim; he has no pain, no congestion of the front of eye, no intolerance of light."

The *lymph-glands* in various parts of the body become swollen at stage of syphilis; we are especially accustomed to look for enlargemen those which lie one above each elbow, and of those that are seated at back of the neck.

Another symptom is partial *alopecia;* the hair may come away with comb so freely that the patient fears becoming prematurely bald. The s hairs from the limbs are shed, as well as those of the scalp.

The cerebral arteries are sometimes diseased at an early date, the more often in the tertiary stage, and, according to Fournier, the same ap to diseases of the cord and nerves.

ory *albuminuria* is not uncommon. Dr Fagge had one patient whose as albuminous at a time when it could hardly be supposed that the had already become lardaceous; and he mentioned two cases of jaun-e of which quickly subsided, but the other ended in acute atrophy of r (cf. Dr Wilks's case, 'Path. Trans.,' 1867, vols. viii and xvii).

present writer has for some years had a patient under observation the subject of secondary syphilis, and passes albumen in his urine any other sign of renal disease.

r syphilides.—After the lapse of the six months, or the year, or two luring which one or more of the early syphilides has developed itself oftener, the disease often becomes altogether latent. In many cases run its course, and the patient henceforth remains perfectly free. other instances he continues to be troubled, at varying intervals, with nanifestations of the disease. Perhaps small scattered pustules on the scalp, which are scratched by the comb, and, scabbing over nd again, cause him great annoyance; perhaps the palm of one w and then becomes scaly and fissured in its centre; perhaps some ails grow rough and thick and discoloured. Affections such as these on for a long time.

in some cases, possibly many months or even years after the subsi-f the early syphilides, there appears one of the late or *tertiary* es, with the characters described above.

1869 a woman was in Guy's Hospital who had been infected by her l twenty years previously, and in whom the disease assumed the form reddish-brown glazed patches, covering the greater part of the face; re not at all raised, and there was only the slightest possible desqua-; in fact, they were scarcely more than maculæ. In other cases, hite scales appear around a red ring or festooned line. Or, again, atches of skin may become thickened, raised, of a reddish-brown and rough with a bran-like scurf. But the most common of the uptions of syphilis are lurid reddish-brown nodules, like those es seen in the early papular syphilide, except that, instead of attered, they now cohere in rings or patches, so as to cover a large or to form straggling festooned lines. Another peculiarity of such lules is that they leave cicatrices even when they have not ulcerated. most instances they either become covered over with crusts or eaten as to form small deep ulcers with vertical edges. It is no uncommon see patches a foot or more in diameter, some parts of which have cicatrised, while others show recent nodules, or serpiginous lines of preading over the healthy skin around them. All these varieties are of the most patient clinical study, for they are absolutely characteristic ilis, and the patient has often no suspicion of their nature. They have l tendency to affect the face (particularly the forehead, nose, and e nape of the neck, the shoulders, the back, and the extensor surfaces imbs.*

r lesions of mucous membranes.—The tertiary period of the disease is

an illustration of the importance of the correct diagnosis of such affections I may he case of a gentleman aged fifty-five, who came to me for the most obviously ulcerating patches, one on each shoulder, which had been steadily getting worse ar. When a young man he had some venereal complaint, attended with swelling stis. He had been married for many years; his wife had had three miscarriages, hildren. Iodide of potassium cured one of the patches in a fortnight, and the hin six weeks.—C. H. F.

also characterised by lesions of the throat and mouth, most of which d from those of the secondary stage. *Plaques opalines* may, indeed, cont to form on the cheeks or lips; but the surface of the tongue now for first time becomes affected in a variety of ways. Sometimes more or extensive patches appear unnaturally smooth and glossy. Sometimes t arise oval greyish ulcers, especially on its centre or edges. Sometime mucous membrane becomes greatly thickened, with deep grooves intersec it in all directions. All these changes render the contact of salt and pe exceedingly painful to the patient, and make him glad to confine himse the blandest possible diet.

In other cases, again, the soft *palate* becomes affected with deep sh cut ulcers, which very rapidly perforate it, and eat away a considerable of its substance. Such ulcers, when they heal, leave well-marked cicatr Some years ago a woman died in Guy's Hospital whose velum had before been extensively destroyed on one side, so that the uvula was hel its place by two thread-like processes of mucous membrane, which looke if they could not possibly have escaped being torn through during deg tion: the preparation is now in our museum. Sometimes the palate become adherent to the pharynx, so as to cut off the communication betv the cavity of the nose and the air passages below.

*Concomitant tertiary lesions and nodes.**—Some writers characterise tertiary period as the "gummatous stage" of the disease. In the su taneous tissue, or in the substance of the tongue, such tumours often acq a very considerable size; and the skin or the mucous membrane over t may at length become ulcerated through, so as to expose a grey degener mass, of the most typical kind. But we cannot call tertiary eruptions matous, to the exclusion of the earlier syphilides. The scattered lenti papules which may constitute one of the first manifestations of cons tional syphilis are not merely inflammatory; and recent observers shown that the nodules which are found in iritis are small gummata, mere fibrinous exudation. Again, Hutchinson has mentioned a cas which definite gummata were found in both testes and also in the spl although a secondary rash was still out on the skin of the patient, died of "syphilitic disease of the heart—myocarditis with a gumma."

The gummatous affections of internal organs are by far the m important of the effects of syphilis, since they produce various sympto and not rarely destroy life. They will be described among the local dise of the meninges, larynx, lungs, liver, &c. It is sufficient here to urge importance of carefully examining the bones and the testes whenev syphilitic taint is suspected.

It is believed that those *bones* which, like the skull-cap, clavicles, u and tibiæ, are but thinly covered with soft parts are more than others li to be affected. By running one finger along the surface of these bones easy to discover whether there is any swelling in them, or whether the pat shrinks from pressure. The enlargement caused by syphilitic perios generally rises gradually from the surrounding surface, but in one inst

* The terms *gumma* and *gummositas* are of considerable antiquity. Fallopius, in sixteenth century, spoke of tumours of bones as having been called "*gummata gallica*," account of their containing a matter resembling *gummi eliquatum*. Ernst Wagner posed to substitute the name "syphiloma" for gumma; but the change is not worth mak "Tubercles" is rightly abandoned, for *tubercula syphilitica* have nothing to do tubercle in the modern sense of the term, although v. Bärensprung supposed that they "Node" is still often used as a synonym of gumma, especially in superficial regions.

ontal and the parietal bones presented bold hemispherical tumours that at ppeared as if they must be malignant growths, especially as one upper was enormously swollen and in part gangrenous: the effect of treat- with iodide of potassium in this case was wonderful. When such s affections are recent they often feel soft and semi-elastic, and at an y one may find that there is a grey succulent material, more or less ively caseating, which can be shelled out of the excavated substance bone. At a later stage the soft substance may be absorbed, and there e left a central depression, with a thickened zone around it. But the bones of the limbs the whole of the gummatous growth is more converted into a uniformly dense, raised, bony mass.

he *testes* are often affected with syphilis in the secondary stage. Later n yellow gummata form in the proper substance of the organ, or epididymis, and can often be easily detected during life. But in cases a diffused fibrous thickening, with atrophy of the secretory ure, is all that one discovers at an autopsy. This suffices to account e fact that so many of these patients are unable to beget children. he could hardly in the living subject recognise such an affection by ion, for flaccidity often may accompany any serious disorder of the l health. Nor, again, is it in itself a proof of syphilis; at least it is in the *post-mortem* room in many cases where there is no other evidence t disease. Still more doubtful is the significance of closure of the nities of the Fallopian tubes in women.

nong the later results of syphilis are *ocular paralysis*, *tabes*, and *ous disease*.

agnosis.—From the foregoing description of syphilis it must be suffi- evident, not only that the recognition of a disease of which the oms and effects are so numerous and varied must often be very difficult, at to attempt to lay down any rules for its diagnosis would be of little Sometimes the first glance at a patient reveals to a skilled observer ture of the case beyond a doubt; and he is bound to treat it actively, ularly in a married woman, without asking questions which might endless domestic misery. In other instances, even when all inquiries pushed without the least reserve, one is unable to arrive at a positive n until one has watched the effects of remedies for a considerable time. nportant to remember that the body should always be stripped as ghly as possible, and that every part of it should be looked at before ronounces as to the character of a doubtful eruption. Some of the puzzling cases are those in which several cutaneous diseases are present same time; as when a macular syphilide is almost hidden among the es of acne indurata or the papules and pustules of scabies.

ansference of contagion.—Few theories in medicine have been better ved than the doctrine of Ricord that primary syphilitic lesions alone s the power of propagating the disease. Clinical experience has fur- numerous instances of contagion from flat condylomata, and experi- have been made which show that it is possible to convey the virus to y persons by inoculation with the blood of syphilitic patients, or with from pustules of a secondary eruption, or from an ulcer of the tonsils. her pus from a late or tertiary affection of the skin contains the poison to be still doubtful. There seems to be no doubt that the surface of

the skin must be abraded, or fissured, to allow of the penetration of the vir and probably this is true even of mucous membranes.

There are undecided questions as to the contagiousness, apart fr admixture with purulent discharge, of the natural secretions of the saliva mammary, or lachrymal glands; of the semen, without impregnation of ovum; or of inflammatory exudation from a mucous membrane—as, instance, the gonorrhœal pus in one who has also had syphilis. With reg to this last point, it is suggested that if pus-cells are wandering leucocy from the blood, they must almost certainly contain any virus which blood itself contains. But it is generally held that the saliva and the n are not in themselves capable of conveying the disease. That mixed flu from the mouth may form the vehicle by which the virus passes from person to another is shown by cases of infection in the act of kissing, glass-blowing, when the same metal tube is employed by different workn in turn, in smoking, if one cigar or pipe is used by several individuals, (as in a case related by Dr Baxter) in cleaning the teeth with anot person's brush. Nor must we forget that we may unintentionally in our patients if we omit thoroughly cleansing a Eustachian catheter o laryngoscopic mirror, after using it in a syphilitic case. The disease also been transferred by one person biting another in the hand. Las accoucheurs and midwives have acquired primary sores on the finger w they have overlooked a slight abrasion upon it during their attendance o woman with flat condylomata or other specific affections of the genitalia.

With regard to the ways in which syphilis is transmitted, it is perh worth notice that among married women of the lower class the diseas often traced back to a confinement, when probably the patient really deri it from her husband after her convalescence, he having become infecte the result of adulterous intercourse while she was in childbed.

Other special pathological points.—Concerning the nature of the prim indurated papule or chancre two opposite opinions are entertained. S think that it is itself a local expression of an infected state of the bl Others, following John Hunter, suppose that the virus does not reach blood until after it has multiplied itself at the seat of inoculation and passed along lymphatic vessels, so as to be discharged with their conte into the great veins. In support of the second view, attention has recen been drawn to the fact that, in the ordinary indolent inguinal bubo, glands which lie along the iliac vessels become swollen as well as those wh lie superficially in the groin. This is said to be shown by three preparati at the Lourcine Hospital in Paris, each of which was taken from a wo who died of some intercurrent disease while suffering from sores upon vulva. But, as Bäumler remarks, if such were the mode of transmissio the syphilitic poison, one would expect that under ordinary circumstan the constitutional symptoms should be longer delayed than when, the s of the primary affection being on the lip or on the finger, only a single gr of glands would have to be traversed. Moreover, even if the *irritation* wh causes the glands to swell does spread from one gland to another, it by means necessarily follows that *infection* of the blood takes place by the s slow and circuitous route. The analogy of vaccination seems to suggest t it is quite possible for an indurated papule or chancre to be the direct re of inoculation of the specific virus *in situ*, and yet for the blood to be alre poisoned from the moment when such a lesion begins to be develop The rarity of multiple primary syphilitic sores, and the fact that the se

a primary sore is scarcely ever inoculable upon the patient, point y in the same direction. One might have expected to settle the point e by excising indurated chancres, or destroying them with caustics r very commencement, but at present the evidence as to the effect of erations is conflicting.

other question concerns the relation between the secondary and the y stages of syphilis. Wilks has long thought that visceral lesions st frequently met with in cases where cutaneous eruptions and other uous symptoms of the disease had been absent or but slightly marked; is opinion has not been positively proved to be correct; and, if it we should still have to ask whether it is not the omission of early treatment in the cases in question which determines the occurrence ote effects. Hutchinson regards the tertiary lesions as sequelæ rather mptoms of syphilis—"regrowths" in morbid structures left behind he secondary period. Of the points which he makes in support of gestion, the most important seems to be the fact that the liability to k of tertiary symptoms sometimes continues after the patient has ed a family of healthy children, and when one can therefore hardly e that his blood still retains the virus.

gnosis.—A patient affected with syphilis is apt to be exceedingly cious in his inquiries as to whether the disease will leave a per- taint. He has heard of instances in which, after the lapse of many tertiary symptoms have appeared; and he has acquired a notion that philitic poison differs from the contagious principles of all other diseases in being never eradicated. But we are probably justified ring him that the distinction is one of degree rather than of kind. immense majority of cases a person who has had syphilis is after a rs free from it in every sense in which it can be said that one who d scarlet fever or smallpox is free from those diseases. In each e the only appreciable difference between the patient and other people he is no longer capable of taking the infection. Nevertheless there any cases in which, notwithstanding careful and long-continued ent, relapses occur again and again. True, they can be cured again ain, but the liability to them seems to be ineradicable.*

inions probably differ widely as to the extent to which the pre- of a syphilitic taint *modifies* other diseases. Some surgeons have hat it may interrupt the natural course of almost every morbid ; that a broken bone may fail to become united, and a wound refuse l, until the virus is neutralised by the administration of specific nes. All this is, however, very doubtful. On the other hand, it is stablished that an injured part may gradually take on the characters yphilitic sore; but then psoriasis or eczema may develop itself upon which have been bruised or lacerated in a person liable to one or the of these diseases. There is no reason to believe that the effects of e diseases like scarlatina or diphtheria on the throat, rheumatism on ints, or psoriasis, scabies, and eczema on the skin, are the least ed by the presence of syphilis, for the two diseases may occasionally n in the same person, each unaffected by the other.

ith regard to *protection*, it is well known that a person very rarely has

n this question see Dr Gowers' somewhat too gloomy statements in his admirable on syphilis ('Brit. Med. Journal,' 1889).

an indurated chancre and afterwards a secondary eruption and sore-throat two different occasions; but several instances of such an occurrence h now been recorded. In a case of Hutchinson's the interval of health only three years; it has generally been much longer. The second att has always been very mild. On the whole syphilis protects against it more perfectly than measles or scarlatina, though perhaps not so perfec as typhus.

The *prognosis* of syphilis depends partly upon the treatment of syphi for over the manifestations of the disease the administration of drugs immense power. To adults, indeed, syphilis is scarcely ever directly fa Bäumler mentions, as the only two ways in which it can destroy hæmorrhage dependent upon spreading ulceration (*phagedæna*), and exha tion appearing when the early symptoms are very acute and severe. only case that has come down to the *post-mortem* room at Guy's Hosp during the last thirty years, in which death was attributed to syphi apart from any visceral lesions, is that of a man, aged thirty-one, who in one of the wards for seven months, with a rupial eruption on the sk and complaining of pain and swelling in his joints. The most extre wasting took place; his knees and his left arm were rapidly contracted; wrists and ankles were enlarged. Towards the last he was drowsy listless, and at the autopsy the brain appeared to contain an excess of flu

Indirectly, as we shall see in the chapters on diseases of the br larynx, lungs, liver, kidneys, syphilis is the cause of a very large mortal If, therefore, its prognosis is almost always favourable, it is because proper treatment we can not only cure the early symptoms, but prev their more dangerous after-effects.

Treatment.—Mercury has been employed as a remedy for syph during nearly four hundred years,* but unfortunately the experience wh appeared to justify its use was long vitiated by an obvious source of err the natural course of the disease, when unmodified by drugs, had never b carefully studied. Moreover, the metal was generally given so freely as cause profuse salivation, with the most pernicious results. Thus, wh certain English army surgeons, in the early part of the present centu introduced a "simple treatment," in which mercury found no place, th had the immense advantage that their patients remained free from ma evils to which persons suffering under syphilis were then commonly s jected by their medical attendants. And what made the difference more striking was that the real nature of syphilis as a specific disease be then altogether unknown, the same methods had been employed indiscri nately for all venereal sores.

It is now an established fact that it is possible for not only the prima lesion of syphilis, but also the various secondary and tertiary eruptions subside spontaneously without any specific treatment; indeed, this res would occur (sooner or later) in most cases if the patient were placed und favourable conditions.

Nevertheless, experience tends irresistibly to the conclusion that patient who has syphilis derives immense advantages from a course of m curial treatment, provided that it is judiciously managed. It has be

* Its use against syphilis was known as early as about 1510, when Fracastorius wrote
Argento melius persolvunt omnia *vivo*
Pars major; miranda etenim vis insita in illo est.—'De Morbo Gallico,' ii, 2

r tried than any other specific remedy, and has stood the test of nulated experience. Among those who throughout the civilised world est qualified to form a judgment upon the matter there is at the nt time hardly any difference of opinion; and what adds to the force is consensus is that it has been arrived at by many paths, after pro- d controversy, and by many who were originally in doubt or in ition.

is certain that mercury, properly administered, is in no way injurious e patient's general health if he is otherwise sound. Even in the case erson with a tubercular tendency, the drug may almost always be given perfect safety, although one should perhaps be more cautious with it. hould the actual existence of visceral disease prevent our prescribing xcept that one naturally would refrain from treating a mild form of lis at all, if the patient were obviously about to die in a few months of sis, cirrhosis of the liver, or renal dropsy.* It is generally thought syphilitic affections attended with much ulceration should, if possible, ated by other remedies rather than mercury, but Hutchinson is now ed to doubt the correctness of this opinion. The cachexia resulting syphilis, so far from being a reason for avoiding mercury, is often ly curable by its use.

Iercury has a most marked effect upon the induration of a primary ing papule or chancre. The treatment of such affections belongs, how- to surgery rather than to medicine.

Iercury if administered systematically during the existence of a ry indurated sore will often prevent the development of secondary toms. This is perhaps more important than any other point connected the treatment of syphilis, and it deserves the most careful verification. resent the best evidence in favour of it is the statement of Mr Hutchin- a paper read before the Hunterian Society in 1874, especially when asted with his previous opinion on the same subject in Dr Reynolds' em of Medicine.' Formerly he thought that secondary symptoms were ne most part inevitable whatever treatment might be adopted. But in es of eleven cases of vaccino-syphilis in which he began to give mercury months after contagion, and about a fortnight after the appearance of pecific induration, not only did every patient quickly get rid of chancre landular enlargement, but only about half of them ever showed secondary toms: these, moreover, were almost always of an exceedingly mild type, lid not appear until many weeks later than they would have done if no cine had been taken. . Now, where syphilis has been intentionally inocu- upon healthy persons constitutional effects have scarcely ever been ing; and the same may be said of cases of vaccino-syphilis in which early rial treatment has not been adopted.

Iercury renders the secondary symptoms of syphilis mild and of duration in proportion as its administration is begun early and is d on regularly and without intermission for a considerable time. this point also Hutchinson has recently spoken very decidedly. erly he cited instances in which a patient, while actually salivated for in one eye, became attacked with the same affection in the other eye, nding to establish an opposite conclusion; but now he says that in such

*Even in such cases the supposed "phthisis" might be syphilitic peribronchitis and itial pneumonia, the supposed "cirrhosis" syphilitic gumma of the liver, and the ed "Bright's disease" lardaceous degeneration from syphilis.

cases the failure is probably due to the fact that the "salivation is pre
ture," that is, that the remedy has not yet exerted its full influence u
the rest of the body, notwithstanding that it has affected the gums
severely. "The secret of success is to avoid any interruption of this kin
and he insists upon the fact that cases in which the secondary symptoms
syphilis are exceptionally severe are almost always cases in which merc
has not been given.

Mercury if administered efficiently during the primary and second
stages of syphilis will probably diminish the frequency and severity
tertiary symptoms. Here, indeed, we come to a point as to which it is
must be difficult to obtain direct proof, for there are no certain data as
the proportion of cases of syphilis which result in tertiary symptoms w
no treatment is used; nor do we yet know to what extent their occurre
may depend upon the severity and character of the secondary sympto
But there is at least a strong presumption that if the drug can prevent
earlier and more constant of the phenomena of syphilis, it will not have
power over the more remote and exceptional effects of the disease.

If these statements are correct, it evidently is the bounden duty o
medical man to prescribe mercury to all patients suffering under primary
secondary syphilis, who place themselves unreservedly under his care.

With regard to the relative advantages of the various preparations
mercury, differences of opinion prevail. We should prefer those which
mild; and it is rarely advisable to prescribe calomel or blue pill, in freque
repeated doses, except, perhaps, when it is necessary to produce a rapid eff
as when iritis or retinitis is present. Plummer's pill is very useful in th
not infrequent cases. It is hard to believe that the hypodermic injectio
the bichloride of mercury has any advantages which counterbalance its p
and its tendency to set up inflammation; yet this is almost exclusively u
as a method of treatment in some Continental cities, where patients unde
hundreds and thousands of subcutaneous or intermuscular injections. T
preparation is better administered by the mouth in doses of one sixteenth
one twelfth of a grain (ʒj—ʒiss of the Pharmacopœial solution) three tim
day. Another preparation which may often be used with advantag
grey powder, in doses of two or three grains: when the gums appear lik
to be too quickly affected, further inconvenience may be obviated by lett
the patient at the same time take the chlorate of potass; but, as a rule, i
not desirable to mask the effect of the mercury in this way.

Sometimes, when no mercurials, taken internally, could be borne, the
unction of blue ointment has succeeded perfectly. But best of all, in re
difficult cases, is the calomel vapour-bath of Mr Lee. About fifteen gr
may be volatilised by a spirit lamp over a water-bath, the apparatus be
placed beneath a chair on which the patient sits naked, and wrapped ro
with blankets. The bath should last from fifteen to twenty minutes.

Except during the cold seasons of the year, the patient may go out,
even continue at his occupation, while he is carrying out a mercurial tr
ment. He should, however, keep early hours and take plenty of rest;
clothing should be made of flannel, and other warm materials; he sho
have good food, but should generally abstain from stimulants. Pure air
important to him; there are greater advantages in residence at the sea-s
than at Aix-la-Chapelle or other Continental spas, where, if report says tr
the real method of cure is neither the baths nor the waters, but mercury.

Even when syphilis has reached the tertiary stage, mercury should, a

be prescribed, if the patient has not already taken it. But in most the remedy which is then most serviceable is Iodide of Potassium. s, indeed, often employed with advantage, even during a protracted lary period; but over the early macular and papular eruptions it has if any power. The most striking effect of this drug is seen in the ment of tertiary nodes and gummata, and of periostitis: over these it has a rapid and sure effect than mercury itself. On the other hand, it does or no good in arterial disease; and after the pains and other symptoms umma have been removed by its use, it is desirable for the patient to go a prolonged course of perchloride or biniodide of mercury. With l to the dose, there has been much difference of opinion. Of late it ecome the general practice to give from ten to twenty grains three a day. It is generally prescribed with aromatic spirit of ammonia. me persons take it more readily in milk, which they keep on a table them and sip from time to time. When the iodide of potassium pro- unpleasant symptoms, they may sometimes be avoided by substituting dium salt. Some patients appear to benefit by this in a remarkable er. Very frequent small doses (four or five grains every or every other is probably the best way of giving either of the iodides when it is tant to bring the patient rapidly under the influence of the remedy.

dide of potassium often exerts so marked an influence over the oms that the patient will go on with it more or less continuously for In such cases it is generally desirable to interrupt its use from time e; and important services are then rendered by the Chlorate of Potass. nate forms of cutaneous eruption may be removed by this salt, given ses of ten grains three times daily. Another medicine prescribed in tervals of specific treatment is dilute nitric acid, and still more valuable is parilla. The fluid extract given in full doses is sometimes followed by estable results. Guaiacum, which three centuries ago had so high a ation as a sudorific in syphilis, has now completely lost it.

is sometimes well to apply remedies directly to the eruptions of lis; some of the local tertiary affections rapidly subside when they are ed with the diluted blue ointment, and calomel should always be dusted mucous patches (*i. e.* flat or moist condylomata). Iodoform ointment ℥j) is the best application to foul and sloughing sores. The severe rnal pains produced by nodes may often be relieved by blistering.

ONGENITAL SYPHILIS.—This is a modification of the disease, which, d of being acquired by direct infection, is transmitted to the patient one or both parents. It differs in some respects from ordinary syphilis symptoms, and is of course without a primary stage. Some modern rs prefer to call it "hereditary" or "inherited," because it does not ly manifest itself by well-marked symptoms until some weeks after The discovery, however, has been made that the bones in the fœtus ften affected by syphilis, and there can be no doubt that the malady, if latent, is really present from the very commencement of extra-uterine ust as it is in an adult during the period of incubation, or in the inter- between successive eruptions. The term hereditary is better reserved iseases such as gout and phthisis, which usually begin at a later age. ase of congenital syphilis does not, it may be observed, raise the difficult ion whether acquired peculiarities are ever transmitted. For syphilis , like supernumerary fingers or scars, a structural variation; nor is it, like

grey hair and gout, the result of a supposed transmitted tendency: it poison which is directly conveyed by a process of infection from the pa to the sperm-cell or the ovum.

Method of transmission.—At one time it was thought that infection to fœtus *in utero* must necessarily come from the mother. But observa proved that in many cases the mother of a syphilitic child showed no of the disease. All writers admit that the semen may convey syp directly to the ovum. A man sometimes transmits the disease to his chil notwithstanding that he did not marry until long after the disappearan all secondary eruptions; but such cases are rare and exceptional. If o consulted about the propriety of marriage on the part of the patient has had syphilis, one should perhaps never declare it to be impossible fo offspring to be tainted: until two years have passed after the complete sidence of the secondary symptoms of the disease marriage must be altoge forbidden; but lapse of time seems, as a rule, quickly to diminish the Hence each succeeding child of the same parents is less likely to suffer the previous one; sooner or later the taint wears out, and the children sequently born remain free. Sometimes, however, one infant may es notwithstanding that both older and younger ones are attacked. There modifying circumstances which may cause the later children of a ma pair to suffer more than the earlier, even when the syphilis had been tracted long previously. A healthy woman, impregnated by a syph husband, gradually becomes herself syphilitic without ever having suf from a primary lesion, so that she forms a second source of infection fo children whom she afterwards brings forth. For there is reason to be that the offspring are much less likely to escape, and that they are often affected severely, when both parents are tainted.

The full extent and subtlety of the contamination which affects the mo of a syphilitic child were first pointed out by Colles, of Dublin, in 1 He formulated the remarkable law which now bears his name, that newly born child, even although it may have symptoms in the mouth, n causes ulceration of the breast which it sucks if it be its mother who su it, though it is still capable of infecting a strange nurse." In other w although the mother may have shown no sign of syphilis, she has yet u gone a modification of the disease, bearing somewhat the same relation t ordinary form that vaccinia does to smallpox, and no less protective i action. The *choc en retour* (as French writers have termed the infection woman through her fœtus) is not, however, always unattended with ptoms. She not infrequently becomes pale and thin, her hair may fal perhaps certain lymphatic glands become swollen, or there may be swelling of bones. Hutchinson has observed that symptoms may first ap at the menopause in the form of so-called "psoriasis palmaris," or sore the tongue. He suggests, as an interesting point for inquiry, the que whether a woman infected in this way *per fœtum* can transmit the tai children subsequently born to a healthy father; one would certainly sup that she could.

Effects on the ovum.—The results of syphilitic infection on the fœtus greatly in different cases. Very often it dies *in utero*, and is thrown off an interval in a more or less decomposed condition, with its cuticle pe in large flakes as the result of maceration in the dark and fœtid liquor a Thus abortions and miscarriages, especially if several times repeated, a valuable indications of a syphilitic taint.

e occurrence of a specific lesion of the *placenta* had long been suspected ; 1863 Dr Wilks cited in the 'Guy's Hospital Reports' some observa- f Mr Wilkinson King, in which the chorion had been found thickened riaceous, and the amnion lined by a false membrane, as the result, it pposed, of syphilis ; in almost every instance abortion had taken place third month. Virchow, however, afterwards described the decidua e maternal part of the placenta as the structures liable to morbid s in this disease. If his view had been correct it would have followed e changes in question must be absent whenever the fœtus derives its n solely from the father ; but there is reason to believe that most hard yellow masses in the placenta which have been taken for gum- ave been mere residues of accidental hæmorrhages. At any rate, ta spreading from the maternal into the fœtal part of the placenta nly once found by Fränkel, of Breslau, who in the 'Archiv für Gynä- ' for 1873 recorded a series of investigations with regard to this sub- In sixteen cases, however, he discovered a peculiar affection of the emselves, a fact of great interest, since it is obviously compatible with ire absence of infection from the mother. The lesion in question s in a dense growth of round- or spindle-cells in the substance of the ttended with a more or less complete destruction and disappearance of ascular loops, and ending ultimately in a process of fatty degeneration. altered are less easily isolated from the structures in which they are ded ; they are swollen and opaque, and have irregular outlines and s extremities. Sometimes the whole placenta is uniformly affected ; en remarkably large and heavy (even to the weight of two pounds), ough, and of a pale greyish-yellow colour. In other instances only portions of it are diseased ; these appear as opaque wedge-shaped surrounded by zones of congestion ; in the healthy portions there en hæmorrhages. Once Fränkel found that the cell-growth had ex- from the villi into the maternal part of the organ. He is in doubt r the premature expulsion of the fœtus, which in his cases took place ing periods from the sixth month onwards, is dependent upon the al lesion directly, or rather upon the death of the fœtus. In some es gestation appeared to have gone on to its natural limit, and he morbid change was partial the child was sometimes born alive. The period at which the affection of the villi was detected was at the nonth ; it often seemed to be only just commencing. We have still n whether a similar lesion exists when abortion occurs at the third or rth month.

casionally a syphilitic fœtus shows gummata in the *liver*, but in the majority of cases what alone characterises the placental disease as tic is a peculiar morbid condition of the *bones*, which is rarely absent. ffection, first described by Wegner, of Berlin, in 'Virchow's Archiv' 70, but independently observed by a French physician, Parrot, at the same time, seems to begin at a very early period of fœtal life. hat which constitutes rickets, it has its chief seat at the meeting etween the shafts of the long bones and their epiphysial cartilages, n the case of the ribs, between their anterior extremities and the ges which tip them. The meeting lines in question become much r than natural, uneven, and irregular. But here the resemblance There is in syphilis comparatively little increase of the normal of proliferation," whereas the "zone of incrustation of cartilage" is

enormously exaggerated. It forms a thick layer, dense and homogene but friable, white, and opaque, like mortar; long processes project fro into the substance of the cartilage beyond. As the affection advances layer becomes separated from the shaft by a soft, or even semi-fluid, grey red or yellowish material, consisting of granulation tissue, which may s off into pus. Another feature is the formation of new bone round the side of the shaft in the neighbourhood of the epiphysis.

Wegner terms this lesion a "syphilitic osteochondritis." It is wi diffused throughout the body, but it is said to be always most marked w the growth of osseous tissue is naturally most active; and what is interes is that precisely the same distribution is stated to obtain in the cas rickets. Thus the lower end of the femur is the favourite seat of diseases, while the corresponding part of the humerus is least often affe by either. Parrot, however, says that in syphilis the new bone is most a dant just where the other changes are least developed; and this corresp exactly with a remark long ago made by Hutchinson to the effect that ostitis in congenital syphilis is more often met with just above the elbow than anywhere else.

In a few exceptional instances, when an infant infected with syphi born alive, the soft material between the shafts of the long bones and epiphyses increases to such an extent as to detach them from one ano and form fluctuating purulent swellings beneath the periosteum. The then complete loss of power in the limbs, attended with so little pain it has actually been mistaken for paralysis. The child's hands are desc by Parrot as lying pronated by its side; its legs are extended, and it is lifted up they hang helpless and swing to and fro. After almost all the principal epiphyses may be found separated from shafts.

Henceforth there ought to be little difficulty in diagnosing cases of severe kind, but it is otherwise with the ordinary form of the disea which there is seldom a sufficient degree of enlargement of the ends of bones to justify one in speaking positively about it, at least in very y infants. Indeed, Köbner has shown that even after death the microsc often required to reveal the presence of the lesion.

These lesions of congenital syphilis are to be carefully distinguished those of Rickets, as will be explained in the chapter on that disease i second volume of this work.

Effects at birth.—As a rule, a child infected with syphilis does not ma symptoms of the disease when it is first born.

One exception is, a peculiar and rare form of bullous eruption, whi known as *pemphigus neonatorum*, and which may either be present at the of birth or come out a few days later. In 1851 there was a discussion this affection in the Academy of Medicine in Paris; Paul Dubois dec that it was syphilitic, while Cazeaux maintained the contrary. Prol in future cases an examination of the bones would easily settle the que The bullæ are flaccid, and contain opaque serum or pus; their favourite are the soles of the feet and the palms of the hands. This eruption gene proves fatal.

The *thymus* has been found in a state of suppuration by Dubois; was no abscess, but the organ when squeezed emitted drops of yell pus, easily distinguishable from the opaline liquid which it may co when in a normal state. Another morbid condition, first pointed ou

ul as occurring in the bodies of syphilitic children, consists in the nce of yellowish-grey indurated nodules in the *lungs*, softening in their es into cavities. Lastly, Gubler has described a peculiar change in the the organ is not only enlarged, hard, and elastic, but its cut surface a number of small, white, opaque grains on a uniform yellowish d. Dr Wilks showed a specimen of this affection at a meeting of the logical Society in 1866; it came from an infant one month old. The is often larger and firmer than usual. Acute peritonitis, or pleurisy, ningitis has sometimes been found to be the cause of death. In cases ortion from syphilis, the state of the skin may suggest the cause of ath of the fœtus.

ffects after birth.—The more common symptoms of congenital syphilis ally begin to show themselves towards the end of the first month of uterine life or in the course of the second month, rarely after the end third month.

he earliest is, in most cases, *nasal catarrh*, producing what is popularly the "snuffles." This is attended with the discharge from the nostrils luid, at first thin and serous, but afterwards viscid, so that it dries up rusts which obstruct the passage of air. Consequently the child is no able to breathe while it is at the breast; it takes the nipple into the only to drop it again, and thus, as Diday pointed out, it fails to get h food, and rapidly loses flesh. Indeed, although syphilitic infants metimes at birth well-grown, plump, and fat, and may even remain so ghout the whole course of the disease, the rule is that they are from rst, or soon become, pale and wasted; they have a dull, opaque, yellow, rinkled skin, and "look like little old men."

oon after the catarrh there appears an *eruption*. Its favourite seats are ates and the face, but it may cover the whole of the body and limbs. It ts of maculæ, blotches, or flat papules, sometimes bright red, but ly brownish or copper-coloured. They are sometimes isolated, some- so confluent that they have been said to look like erysipelas. It is times difficult to distinguish between syphilis and the effects of the 's negligence in allowing the parts about the anus to remain soiled with ta, or in drying them insufficiently after washing. As a rule, however, ed blush produced by mere irritation is ill-defined and fades away at dge, whereas at the margin of a specific rash there are seen isolated, ly outlined blotches. The inflamed surface, moreover, is uniform and t red in ordinary dermatitis, it is patchy and yellowish or coppery in caused by syphilis. The papules themselves may have smooth and l surfaces, or they may be dry and horny, raised here and there into l bullæ, or superficially ulcerated. At the corners of the eyes, about ngles of the mouth, in the folds of the neck or of the groins, or round nus, the papules often become covered with a moist opaque layer, and e more or less the appearance of flat condylomata. But typical ous patches," occurring chiefly at the anus, are comparatively seldom n children less than eight or ten months old. Sometimes the eruption a pustular form; the greater part of the body may then become ed with moist scabs, separated by cracks, from which a sero-purulent is constantly oozing.

the interior of the mouth ulcers are often present, or there may be a e *stomatitis*. The latter affection involves the gums and dental sacs; inson has seen it lead to necrosis and exfoliation of the alveoli. The

mucous membrane of the nose may likewise ulcerate, and dischar sanious fluid, perhaps containing fragments of bone from the septum.

Another but a rare symptom is *iritis*. Of this Hutchinson, some y ago, cited twenty-three cases, the majority of which occurred in girls. was usually seen at about the age of five weeks. Sometimes it was lim to one eye, sometimes it affected both eyes. It was attended with irr larity of the pupil, alteration of colour in the iris, and the exudatio white, yellow, or red lymph. But it required to be carefully looked fo the cornea was generally clear, with only a faint pink zone round its mar

Transference from the child.—Although, in accordance with Colles's la child suffering under congenital syphilis is incapable of infecting its mot it may give the disease to any other woman who suckles it. Diday records cases in which women advanced in years appear to have contra syphilis by kissing such infants; and the use of a spoon that had previo been employed in feeding them has been followed by the same terrible co quences. Probably the source of the virus is always the secretion o ulcer about the lips or within the mouth. Hence Diday lays great stres the importance of searching for such ulcers, when a child born of syphi parents is to be placed with a wet-nurse. But as it is practically impos to be sure that the back of the throat is healthy, French writers advise as soon as any cutaneous eruption, or even a nasal catarrh is discover one should, for the nurse's sake, insist that she should no longer suckle an infant. If one knew of a wet-nurse who had had syphilis she migh engaged for the service; but otherwise recourse must be had to the feed bottle. The primary lesion on the nipple of a nurse is described by Di as a small red papule, slightly desquamating on the surface. When infected, she in her turn may convey the disease to other infants. That milk is not the vehicle of the poison is shown by an observation of Henry Lee's. A woman, who was nursing a syphilitic child with one br acquired an ulcer upon that breast, and afterwards an eruption; but own infant, for whom she reserved the other breast, went on sucking for weeks and remained healthy.

Syphilis contracted by an infant from a wet-nurse does not appea differ in its symptoms from the inherited form of the disease.

Later effects.—The subsidence of the usual symptoms of congenital syp is occasionally followed by the development of others, which are obvio analogous to those that constitute the "tertiary" stage of syphilis in adult. Thus nodes may appear. Hutchinson says that the bone most o affected by them is the humerus at its lower end, and that they often reach a size as to impair the movements of the elbow-joint. A girl of eight or years old originally came to Guy's Hospital on account of large ulcerati rupial patches, covered with thick brown crusts, on her trunk and li Under iodide of potassium they healed with marvellous rapidity, but nevertheless returned with extensive periosteal swellings upon the tibia ulna, and it was two or three years before she was finally cured. Ano form of eruption consists of raised red rings or zones, somewhat like "circinate squamous syphilide" of adults. At the Evelina Hospital we had a girl, eight or ten years old, with a sloughing ulcer which had destro the soft palate, and with great enlargement of the metacarpal bones of hand. Hutchinson cites the case of a boy, aged eight, almost the whol whose calvaria was involved in disease at first regarded as "strumous," which proved to be syphilitic; he was the son of a clergyman, but his mo

ontracted the disease from a former husband, an officer in the army. lar swellings, doubtless gummata, in syphilitic children's testes have or twice been found at Guy's Hospital after death. Of lardaceous se, as the result of congenital syphilis, nothing appears to be known.

he most interesting of the remote effects of the hereditary disease are, ver, some which differ altogether from those of ordinary acquired syphilis. discovery is due to the acumen and patience in observation of Mr hinson, to whose masterly account very little has been added by any rs but himself. One peculiarity is that on each side of the forehead *ontal eminence is protuberant.* M. Parrot maintained that, in addition to ntra-uterine osseous lesions already described, syphilis gives rise, during infancy and childhood, to a morbid change in the bones resembling that kets; and Hutchinson now accepts this account of the appearance in ion. A character on which Parrot has further insisted is the presence of eminences upon the bones forming the sides of the anterior fontanelle; their resemblance to the buttocks he calls such a calvaria "natiform." lso claims for congenital syphilis the affection known as Craniotabes, has hitherto been deemed rachitic. But this is more doubtful.*

he other signs of congenital syphilis established by Hutchinson are far distinctive than the shape of the forehead. One is a *sunken bridge of the* resulting from long-continued swelling of the parts within, or from loss pport by exfoliation of the septum. Another is the presence of radi- *linear cicatrices* at the angles of the mouth, running outwards towards heeks. A third is a thick, pasty, opaque condition of *the skin*, the hair scanty, and the nails broken and apt to split.

Most characteristic of all is a peculiar change in certain of the permanent and particularly in the *central upper incisors*, which for this purpose hinson terms the "test-teeth." Not only are they much smaller than but they are "notched" and "pegged;" the former peculiarity con- g in a single deep crescentic excavation of their free edge, the latter gradual convergence of their sides towards this edge. It is supposed his alteration in their form is the result of their having been disturbed eir growth by the stomatitis which is so marked a feature of the dis- during infancy. When they first protrude from the gums the notch is present; in its place there is a row of minute projections; these soon wards break off. Similar changes may sometimes be observed in the of the other incisors. It is important to note that the above single notch is alone indicative of syphilis. Horizontal grooves on the sur- and numerous small notches in the edge, are common enough in per- who are altogether free from any congenital taint. Also, it is certain the defect of the teeth due to mercurial salivation during dentition is distinct from that of syphilis.

he appearances just described enabled Hutchinson to identify as litic an affection of the eye, the real nature of which had not previously suspected, and which was always known as "strumous corneitis." e can be no doubt that the "ugly form" of scrofula described by on and other writers was for the most part syphilitic, just as the tty form" was tubercular. *Interstitial keratitis*, as it is now called, occurs y in children between eight and fifteen years old, but sometimes in s up to the age of twenty-five or twenty-six. It is more common in girls n boys. It seldom remains limited to one eye, but commonly attacks both

* See on this and other points Fournier's 'La Syphilis héréditaire tardive,' 1886.

in succession at an interval of a few weeks. It begins as a dotted haz near the centre of the cornea, which spreads until almost the whole of opaque, like ground glass. The patient often complains but little of int ance of light, and there is not generally much congestion of the conjun or sclerotic at first. Ulceration never occurs, but at a certain stag cornea may become so vascular as to be uniformly pink or salmon-colo When the affection is at its worst, vision is often reduced to a bare pe tion of light; but in the course of a year or eighteen months a surpr degree of improvement takes place. The opacity slowly clears up, perhaps only a few hazy patches remain; and the patient's vision ultimately be little impaired. Sometimes iritis occurs as a complicatio choroido-retinitis. Interstitial keratitis is very rare in acquired syphil

Another morbid condition occasionally seen in the subjects of congo syphilis is *deafness*, apparently from some disease of the deeper par both ears. It belongs to the same age as interstitial keratitis.

Protection.—Is a subject of congenital syphilis less liable than o to acquire the disease later on in life? Hutchinson has recorded inst in which chancres have been contracted under such circumstances, an in which constitutional symptoms occurred; and his opinion is that th of a patient's parents having had syphilis renders the acquired di milder but does not altogether prevent it.

Transmission.—Is it possible for the taint to be handed down to a generation? Hutchinson has about eight times had opportunities of ex ing the children of persons undoubtedly the subjects of congenital syp and with one exception they appeared to be healthy.

Treatment.—Congenital syphilis seldom proves directly fatal, except after birth. In mild cases the eruption may subside in a few weeks wi treatment; and in the more severe forms of the disease specific treat is very successful. The usual plan is to prescribe the mercury chalk powder, in doses of a grain or two grains, two or three times a according to the age of the infant; a minute quantity of Dover's pow or of carbonate of soda may be given with it, according to circumsta Many prefer, however, to use the diluted mercurial ointment externall may be applied on the inside of a flannel band which is sewn round the as Sir Benjamin Brodie recommended; or ten or fifteen grains of it be rubbed into the child's armpits once or twice daily for a few minutes time; or the solution of perchloride of mercury may be ordered in of ♏xx to ♏xxx three times a day. Mucous patches about the anus be dusted over with calomel.

In the later forms of congenital lues, mercury and potassic iodide a be used as in the acquired disease, and they are no less efficacious.

TUBERCULOSIS

these facts speak as it appears to me so eloquently and decisively for the infectious
Tuberculosis, that we are not shaken in this conviction by the direct demon-
of the tuberculous virus being up to the present time an unsolved problem."

COHNHEIM, 1881.

of the most important diseases which, under various forms and ry different local characters, affects almost every organ of the body rculosis; and this must now be included in the extensive group of infective fevers. Like syphilis, it usually comes before us as a chronic and it differs widely in its clinical aspect from the continued fevers nthems, particularly in the apparent absence of an origin from con- but in this respect it does not differ widely from pyæmia, or even teric fever, erysipelas, and diphtheria, in all of which it is difficult to trate a specific and constant contagion.

presence of the infecting virus is so wide-spread that it is absent few parts of the world, but susceptibility to it is happily far less ; hence the predisposing causes are much more important in this any other infective disease. The healthiest organisms appear to have any power of resisting the invasion of smallpox or of plague, but re exposed to scarlatina who do not take it; and this power of re- is far more common in the case of tubercle.

en the virus has gained an entrance it is most active locally. ntoxication" of the lymph, blood, and tissues is less rapid, and less complete, than in the typical specific fevers; there is, in fact, a ation of local granuloma-growths (the tubercles) with general febrile ance (so-called hectic fever). In this respect it forms one of a f infective maladies, from purely general to purely local: typhus, , syphilis, tubercle, leprosy, lupus.

remarkable are the affinities of tubercle to specific fevers that Cohn- redicted that one day phthisis and other tubercular maladies would rded as due to a specific contagium: see the passage at the head of pter from his 'Vorlesungen ü. allg. Pathologie' (Bd. ii, S. 709–712). s prediction has been fulfilled by Koch's discovery of the bacillus of .

We must not commit the error of ascribing all the symptoms and m changes of tuberculous diseases to this cause; they are local inflamma as well as specific infective lesions, so that we shall best consult patholo accuracy as well as practical use by treating in this place of tubercu generally, among specific fevers, and leaving the account of its local var to the chapters which relate to diseases of the brain, of the lungs, abdo and other parts; just as we have dealt with syphilis as a specific dis among infective fevers, and reserve the account of its local effec subsequent parts of this book.

Anatomy of tubercle.—One great stumbling-block in the way of a understanding of tubercles has been imperfect observation of the chang appearance which they present in different stages of their forma Laennec described them as first "having the appearance of small semi-t parent grains, greyish or colourless, varying from the size of a millet to that of a hemp seed. . . . Afterwards they gradually increa size, and as they do so they become yellowish and opaque, beginning i centre. . . . Several unite together to form larger masses, pale ye opaque, and of the consistence of very firm cheese. . . . At l they soften and finally liquefy; this change also begins in the centre progressively approaches the circumference." The grey semi-transp granules he termed "miliary tubercle;" to the yellow cheesy mass applied the unfortunate name of "crude or immature tubercle."

Louis, whom Laennec's premature death left the leading patholog Paris, limited the application of the word tubercle to the yellow op stage, his method of statement being that the grey semi-transparent gra "undergo conversion into tuberculous matter." By most subsequent w the early grey stage was passed over altogether. Perhaps they wer fluenced by the misleading term "crude" tubercle, applied to the yellow s At any rate, they taught that the yellow material was deposited as such the blood.

Virchow, therefore, effected a most important reform of pathological trine when he showed that a yellow cheesy substance, identical with "cr tubercle, may arise out of decaying matters of various kinds, from ordi inflammatory exudations up to sarcoma and carcinoma; in other words, caseation is merely a mode of retrograde metamorphosis. Neverth Virchow certainly underrated the extent to which cheesy masses in the l and in other organs are really of tuberculous origin; though he never so far as one or two of his followers, who almost deny that tubercles ca at all.

A proof that grey and yellow tubercles may be stages of the morbid product is, as Louis long ago pointed out, that the successive ch described by Laennec may often be observed to occupy definite positio the lung; towards the base there are grey semi-transparent tubercles; hi up they are of opaline aspect and yellowish in their interior; higher still are yellowish-white throughout their entire substance. He might added that they become larger and approach one another more closely below upwards. Now, since it is certain that the upper lobe of the lu almost always the earliest seat of tubercles, and that they gradually sp downwards through the organ, the conclusion seems indisputable that are first grey and afterwards become yellow. It is, however, also true tubercles often undergo caseation before they are large enough to be vi

the naked eye. Both in the pia mater and in the liver the writer has
ıtedly found tubercles of microscopic size which were already opaque, not
in the centre, but in the greater part of their substance. It is therefore
possible that no grey tubercles may be discoverable in a diseased organ,
when tuberculosis has been rapidly destroying it. Again, another fact,
h is still more important, is that tubercles, instead of caseating, often
ergo a different change, which leaves them permanently grey. The earliest
rvation of tubercles in this condition dates further back than the writings
aennec himself. A few years before the publication of his great work,
827, another French physician, Bayle, had divided phthisis into different
es, only the first of which was termed by him "tuberculous." To the
nd species he gave the name of "Granular Phthisis," and described the
s as "stuffed with transparent shining granulations, of cartilaginous
re and consistence, never opaque, and without any tendency to soften."
, it is a curious circumstance that those pathologists who (as we have
) came to regard a yellow cheesy condition as typical of tubercle, habitu-
spoke of *recently-formed* grey tubercles as the "grey granulations of
e;" yet a perusal of the four cases of granular phthisis, related in detail
hat writer, shows clearly that in three of them, at any rate, the disease
of a *chronic* kind. Such a degree of hardness as he attributes to his granu-
ns is, indeed, inconsistent with their having reached only an early stage
eir development; and he also expressly mentions that they are some-
s pigmented or speckled with brilliant black dots and lines, which will
nown elsewhere to be characteristic of *chronic* tuberculous affections of the
s and bronchial glands. In fact the grey granulations of Bayle are really
rcles which, instead of caseating, have undergone a fibroid change, and
thus become permanently hard and semi-transparent.

Miliary tubercles, then, may be of three kinds:

1. *Soft grey granulations*, always of recent formation, and essentially tran-
y in their characters.

2. *Yellow granulations*, of either recent or old formation, tending, if they
ergo further change, to soften or liquefy.

3. *Hard grey granulations*, always chronic, and liable to no change, except
ientation.

Histological characters of tubercle.—It may well be supposed that histolo-
s have had much to say with regard to the nature of the tubercular
ess. But the present writer ventures to think that their views on this
ect are fundamentally erroneous. Their object has been to discover
e microscopical characters which should serve to distinguish tubercular
ns from all others. Thus Lebert many years ago thought that he had
d a specific "*tubercle-corpuscle*" in the yellow cheesy material which was
hat time taken for the typical form of the morbid product. Since
how taught that this material is already in a state of decay and degene-
on, the search has been actively prosecuted in tubercles still grey and
nt. Virchow himself held that their histology is that of a form of
our, namely, *lymphoma;* according to him, individual tubercles are com-
ble with the Malpighian bodies of the spleen; and, as he believed that
are apt to arise where no such lymphoid structures are naturally
ent, he regarded them as "heteroplastic" new growths. Subsequent
ers further developed this view by insisting on the existence of a reticu-
d stroma, such as belongs to other lymphomata. It was also suggested
the true seat of tubercles was perhaps the interior of the lymph-

channels throughout the body, and that their cells might probably formed by a proliferation of the lymphatic endothelium. On the ot hand, Dr Sanderson endeavoured, in 1868, to demonstrate in those part which tubercles occur the normal presence of lymphoid tissue, an o growth of which might lead to their formation, and thus render th "homœoplastic."

But about that time the attention of histologists became drawn another element of tubercle, which has played a principal part in various theories that have since been advanced. That very large cells sometimes to be found in a tubercle had long been known; Virchow hims described cells containing twelve or more nuclei. Langhans and Schüp now insisted on the frequent presence of such bodies, and applied to th the name *Riesenzellen* or giant-cells, which had previously been invented Virchow for similar corpuscles in certain sarcomatous tumours (v. *supra*, 80). According to Dr Hamilton, whose papers in the 'Practitioner' 1880 are illustrated by beautiful drawings, giant-cells occur with the utm regularity in all tubercles. They are from ten to thirty or forty tin larger than the lymphoid cells, which are also present. They are so times placed in the centre of a tubercle, sometimes laterally. When giant-cell is young, it seems to consist of a large mass of granular pro plasm, sometimes with many nuclei in it, sometimes without them. A grows older, the peripheral part of it (the "periblast") becomes organis and constitutes an almost fibrous sheath, in which great numbers of rou or oval nuclei may be perceived, and from which ultimately processes ar in continuity with the reticulated stroma of the rest of the tuber Further on, Dr Hamilton speaks of a tubercle as made up of one or m "giant-cell systems." He imagines that even the "lymphoid" and "e thelioid" cells which are found in the tubercle have originally been c nective-tissue nuclei, which have become detached and thrown off into t meshes of the reticulum.

Histologists are by no means agreed as to the origin of the giant-cells tubercle. Dr Hamilton's view is that each of them arises by the p gressive growth of a single large connective-tissue element. But Schüp himself attributed them to the coalescence of leucocytes in the interior capillary vessels. And both Dr Klein and Prof. Julius Arnold ha recently stated that they may be produced by the fusion together of number of epithelial cells, of which the nuclei persist. If such opinio are correct, it is impossible that giant-cells can possess the significance regard to tubercles which Dr Hamilton and others would assign to the After all, giant-cells are far from being as conspicuous or as easily demo strable elements in a tubercle as they are in a myeloid sarcoma.

Again, the conception of giant-cells as the essential and distinguishi elements of tubercles has of late years been rudely shaken from anoth side. The experiments of Ziegler, quoted above (p. 56) have show what had been to some extent recognised before him, that giant-cells a formed in ordinary inflammatory exudation, during the course of i "organisation" or development into tissue. In fact, Ziegler's researche were undertaken with the special object of throwing light upon the stru ture of tubercle, and upon the relations between tuberculosis and inflamm tion. Moreover, nodules, having the histological characters of tubercle but of microscopic size, had already been found by other observers in plac where their presence certainly would not have been expected. Köster di

ed tubercles (sometimes visible even by the naked eye) in the granula- which project into the interior of diseased joints; and Friedländer similar bodies constantly present in lupus and in the walls of scro- ulcers. It is true that both these affections were previously believed ar a more or less close relation to tubercle. But it is impossible to he same of certain other lesions in which Friedländer or Köster ohnheim found microscopic tubercles. Among them are a shallow of the uterus in an old woman who died of apoplexy, the stroma of a rous tumour, the floor of a phagedænic chancre, and bands of adhesion pleura or in the peritoneum. Friedländer, indeed, maintains that all cases are examples of "a local tuberculosis," and compares them with fulous testis, or with pulmonary phthisis, which does lead to a general culosis. But this is surely a strained and partial view of the facts.

robable connection of tubercle with inflammatory exudation.—The general usion which we may draw from all these observations with regard to istology of tubercle is that there is nothing in them to prevent our ting the doctrine that *Tuberculosis is a modification of the inflammatory s*, if it is commended to us on other grounds. Some of the reasons led the author of this chapter to accept it will be stated further on; apart from these, it seems to afford the only possible solution of a lty which histologists used to regard as insuperable. Niemeyer's denial tubercles are an essential feature of pulmonary phthisis was based on icroscopical observation that in many specimens of phthisical lungs the d process which precedes the occurrence of caseation is not a deve- nt of lymphoid tissue, but a filling of the alveoli with epithelial cells, other words, a "catarrhal pneumonia." He accordingly declared that nic catarrhal pneumonia, ending in cheesy infiltration, really constitutes rimary anatomical lesion in many cases of phthisis. His opinions have been adopted by many other pathologists. Dr Hamilton, for example, s that dry yellow nodules, such as were described in the lungs by ec, are generally nothing but patches of catarrhal pneumonia; bodies g an aspect similar to that of a tubercle, but as large as millet seeds, ly (he says) prove to be groups of air-vesicles affected with catarrhal monia. But it is the greatest mistake to suppose that the cases in catarrhal pneumonia must be separated from tuberculosis can be d to those of ordinary phthisis, if the separation is to be made at all. he contrary, the principal point on which Dr Wilson Fox insisted in ng the discussion on tubercle at the Pathological Society in 1873 was in the disease known as acute tuberculosis, occurring in children, lations "composed of epithelial proliferation" are generally found in numbers than those made up of lymphatic cells. And in that very a German observer, Hering, actually went so far as to declare that the ary fatal miliary tuberculosis of the lungs ought to have its name ged into that of acute disseminated catarrhal pneumonia. But this l, after all, leave the difficulty untouched; because, as Dr Fox pointed granulations made up of an interstitial small cell-growth are generally resent in such cases, and some granulations consist partly of one kind ments, partly of the other. Moreover, it has been shown by Julius d that precisely similar epithelial changes to those in the lungs occur liver and in the kidneys, when affected by acute tuberculosis; while has demonstrated a caseating catarrh of the seminal tubules in the so-

called scrofulous disease of the testis. Now, if the tuberculous proces regarded as a modification of inflammation, it is possible to solve the culty without giving up the use of the term tubercle, and without igno the important distinctions that undoubtedly exist between ordinary inf matory affections and those that are tuberculous. The relation of catar inflammation to the inflammatory process in general is still imperfe understood (cf. *supra*, p. 51). But at least this is certain, that the s kind of irritation which in most other tissues leads to an exudatio leucocytes, causes, when applied to epithelial tissues, an overgrowth epithelial cells. Ziegler argued that a tubercle owes its rounded form its definite size (varying only within rather narrow limits) to the fact tha is produced by the circumscribed action of an irritant of but slight inten upon the spot which afterwards becomes its centre; and he contrasts effect of such an irritant with the far more powerful operation of a se particle, such as gives rise to a miliary abscess. Now it is easy to conc that whereas the circumscribed irritation of a minute area of connec tissue results in the formation of a granulation made up mainly of le cytes, the same kind of irritation applied to an epithelial area may cau granulation consisting of epithelial cells. The two bodies may differ c pletely in their histology, and yet we may be quite right in giving bot them the same name. It is from this point of view that the attempt to a criterion of tubercle in its histological structure appears to be fundament erroneous.

Specific character of tubercular inflammation: infiltrating tubercle.—The ception of tubercle unfolded in the last paragraph is one which Dr F for several years past taught in his lectures on pathology. Koch's disco of a tubercle-bacillus supplied the "irritant of but slight intensity" tha needed for the theory. The slow growth of this organism, to which K himself draws attention, accounts for the fact that the morbid process wh results from its action is so much less acute than infective inflammation general, with which tuberculosis must henceforth be regarded as c parable.

It is not the least advantage of this view of tubercle that it enables u understand how an affection (whether of the lung or of any other org may fail to present the characteristic granulations, and yet be really tu culous. Laennec long ago described what he termed a tuberculous "infil tion of the lungs," when considerable portions of the pulmonary tissue bec solidified by a greyish and semi-transparent, or by a paler and yellowish-wh material; either without any previous development of distinct tubercles, around tubercles already formed. Subsequent observers have very gener declared such lesions to be "pneumonic." But in their naked-eye charact these "infiltrations" differ altogether from anything that is seen in ordin pneumonia. Even when the growing edge of a patch of pinkish-grey filtration appears quite homogeneous, one often finds that the less rec parts of it, where caseation is commencing, show yellow granulations cor sponding exactly with tubercles in size and in general appearan Now, it is easy to see how a uniform consolidation may result from t irritation set up by bacilli if they happen to lie very close to one anot through the pulmonary tissue. Again, in association with acute tubercul of other organs, an affection of the membranes of the brain is not frequent, which seems to be a simple inflammation, since no tubercles discoverable. In such cases, the presence of recently formed tubercl

here is strong evidence that the meningitis must be essentially of the nature.

aseation of tubercle.—Another peculiarity of tubercular lesions, which is ly less characteristic than the presence of the grey granulations, e tendency to caseate. Most pathologists since Virchow have been eady to assume that caseation is of frequent occurrence in merely mmatory affections. It is of course indisputable that the pus con- l in a serous sac or in a large abscess may, and often does, dry up into esy mass. The same thing is observed in the crypts of the tonsils, in ecal appendix, and in other pouches of mucous membrane, and it is n the walls of arteries when they become atheromatous. But in every f these instances the inflammatory exudation which caseates is more or eyond the range of the blood-vessels. Is it a fact that simple inflamma- ver leads to caseation in the substances of a vascular solid organ—in iver, or in the spleen, or even in a lymph-gland—unless a definite ss has been formed? Such an occurrence is commonly spoken of as if re the most natural thing possible; but it would be difficult to find nces that will bear hostile criticism. Surely, in a healthy person mmation generally runs its course so as to leave no *débris* behind, except an abscess forms and fails to discharge itself. In the solitary follicles e intestine it used to be supposed that caseation was often met with, independently of the tuberculous process; but the writer's own experi- has been that it scarcely ever occurs unless other parts of the body in tubercular lesions.

ne of the most typical features of tuberculosis is the presence of ding ulcers in cavities, with yellow walls of definite thickness, the nce of which regularly undergoes caseation almost as soon as it is d. This process, wherever found, whether as a pulmonary vomica, the liver, the kidney, the prostate, or the testicle, may be safely set as tuberculosis.

hose pathologists who have recognised that caseation is especially apt ur in tuberculous lesions have commonly attributed it to the absence od-vessels in tubercles. Thus Virchow's comparison between tubercles he Malpighian bodies of the spleen was objected to, and with justice, e ground that the latter contain capillaries. Every museum of morbid my contains injected specimens of phthisical lungs, from which it appears not only isolated tubercles, but also patches of caseous infiltration, are utely non-vascular. No new vessels seem to be formed in them, and re-existing vessels of the pulmonary tissue undergo obliteration. The er process of softening and liquefaction, by which vomicæ are formed, rs to be essentially of a chemical nature.

ibroid transformation.—In many cases, as already mentioned, tubercles, d of caseating, undergo fibroid transformation. What determines them e the one course rather than the other is as yet uncertain; but it would that caseation is less frequent in proportion as the patient is older. In s other than the lungs, comparatively little is known about "fibroid" cles. But Schüppel has demonstrated their occurrence in lymph-glands, as shown that the reticulated stroma grows at the expense of the cells, s converted into a transparent, almost homogeneous, indistinctly fibril- material; and Rindfleisch has recorded a remarkable specimen of s tubercles in the great omentum. The occurrence of a similar change bercular infiltration is, probably, the origin of the disease known as

fibroid phthisis. Even in such cases, there seems still to be defici vascularity; for Rindfleisch has insisted on the impossibility of forcing in tion into the interior of indurated masses in the lungs, and contrasts t state with the abundant supply of vessels to the newly formed connec tissue in cirrhosis of the liver and in granular disease of the kidn No writer has laid more stress on the fibrous transformation of tubercles t Dr Hamilton, who, indeed, declares that the natural ultimate destiny of th bodies is to become little fibrous tumours, and that many of the so-cal cirrhoses of organs, both in children and in adults, are in reality the rem of outbreaks of tubercle.

The tubercle-bacillus.—In the 'Berliner klinische Wochenschrift' for A 10th, 1882, Dr Koch made known the important fact that he had discove bacilli in the tubercular diseases of man and of animals,* that he had succee in cultivating these bacilli upon the coagulated serum of blood, and had b able to set up tuberculosis in healthy animals by inoculating the cultiva products. The organisms themselves he described as in length equal t quarter or half the diameter of a red blood-disc (3–5 μ), and in breadth fifth to one sixth of their length. They are slightly curved and have roun ends. When prepared by a particular method of double staining,† t present a blue colour, whereas nuclei and other tissue-elements appear bro This not only facilitates their recognition, but also serves as a point of tinction between them and all other kinds of bacilli, except those of lepr which, indeed, resemble them very closely, and only differ in being still n slender and in having pointed ends. The bacilli of tubercle, while lying in living tissues, produce spores which are oval in form, from two to fou number, and placed at equal distances in their length so as to give the ba a beaded appearance. When grown upon the coagulum of blood-serum, organisms become aggregated together into flat, scale-like masses, hardl large as poppy seeds, which can be lifted off entire, and which are so t that it requires some force to break them up. Their development takes p very slowly, about ten days elapsing after infection of the coagulum be any change is discoverable. Another condition necessary to their growt a uniform temperature of 86°—106° F. Hence they cannot grow in open air in this climate.

Koch does not think that previous observers who have described mi cocci,‡ or even rod-shaped bodies, in tubercle, had seen the same organi which were discovered by him. They are not generally present in la numbers, except where the tuberculous process is recent and acti if it is slow, they are often to be found only within the giant-ce perhaps one or two in each cell. They do not exhibit spontaneous mo ment.

The original cases in which Koch found his bacilli were the followi (1) Eleven cases of miliary tuberculosis. In miliary tubercles of the lu

* There is still some doubt as to the identity of Perlsucht in cattle (v. *infra*, p. with tubercle in man. Klein finds that the tubercle-bacilli in man are much larger t those in the tubercular lungs of cattle.

vious experiments on the artificial production of tubercle.—Koch's discovery
utes the final link in a chain of evidence which has been long accu-
ng, and which places tuberculosis among the specific diseases. In
French observer, M. Villemin, made known a fact which roused the
t interest in the medical world; he found that in certain animals,
larly rabbits and guinea-pigs, tuberculosis could be set up by the
tion of tuberculous matter from the human subject. His experiments
on repeated in this country by Mr Simon, Dr Sanderson, Dr Wilson
nd others. Tubercles from the pia mater or from serous membranes,
substances from the lungs of phthisical patients, even the sputa yielded
n patients during life, were introduced beneath the skin of animals.
were afterwards killed, or were allowed to die of the disease which
d the operation and generally proved fatal in from six to ten weeks.
then found that pus or a dry, cheesy substance had been formed at
t of inoculation, and that bands of induration extended away from it into
acent subcutaneous tissue. The lymph-glands in the neighbourhood
nlarged and caseous. Nodules of various sizes were present in the
the liver, the spleen, and the peritoneum. These resembled tubercles
the naked eye and in their histology. They consisted of a grey,
ansparent material, which underwent caseation from the centre out-
The infective character of the process was further shown by the fact
atter taken from the body of an animal after death was capable of
up the same disease in other animals.

er a time, however, certain observations were made which seemed to
ne bearing of these experiments. Dr Sanderson found that in guinea-
"artificial tuberculosis" arose after the inoculation of pus from the
ary abscesses of pyæmic patients, or even after the mere introduction
an seton of unbleached cotton. Dr Wilson Fox independently arrived
ke result by inoculating guinea-pigs with pieces of putrid muscle, or
accine lymph. In Germany, Cohnheim and Fränkel introduced into
ritoneal cavity of animals of the same species portions of new growths,
of healthy organs from the human body, or even bits of charpie or
ercha; and they succeeded in setting up a tubercular process not only
serous cavity itself, but also in the lungs and in the liver. It even
ed that guinea-pigs in which incisions were made, without any injec-
erished afterwards with inspissated abscess at the seat of injury, and
iliary tubercles in their organs; so that it became necessary to give
erimenting upon such animals, and to have recourse to dogs, as not

the twenty-first volume of the 'St Bartholomew's Hospital Reports,' Dr Vincent
states that in twelve ancient specimens of tuberculous lungs, from forty to seventy
d, he succeeded in demonstrating the presence of Koch's bacillus microscopically.

being liable to be made tuberculous by trifling wounds. But, after injec into the jugular veins of these dogs pus from guinea-pigs which had th selves been inoculated with non-tuberculous materials, it was found that dogs likewise became the victims of miliary tuberculosis.

These observations fitted in perfectly with a theory of tuberculosis w had been propounded a few years before the publication of Villemin's exp ments, but which at the time had attracted little notice. In 1857, Bul Munich, had suggested that in the human subject acute miliary tubercu was due to the absorption into the blood of caseous matters from non-en suled yellow tubercles, or from pulmonary cavities not surrounded on sides by dense fibroid tissue. Indeed, a similar opinion had been expre earlier still by Dittrich, of Erlangen. It afterwards became the fashio regard tubercle as always a secondary product, the origin of which was so for in "caseous foci," of which the formation was supposed to precede, i cases, the development of tuberculous lesions. In ordinary cases of pht it was thought that a catarrhal pneumonia, with secondary more or extensive caseation, was the earliest change, and that this might go on great length of time before any tubercles made their appearance, so perhaps the disease might become tubercular only at its very end. Su view was of course in entire accordance with the doctrine of Niem already referred to (p. 310). The acute tuberculosis of children was tr back, in a large number of instances, to a simple intestinal or bron catarrh; this was supposed to lead first to swelling of the correspon abdominal or thoracic lymph-glands, and then to their caseation; and once caseation had commenced the conditions for the development of tub were assumed to be present. Dr Hamilton still maintains this doctrine imagines that in the process of caseation some material, probably a ferm is elaborated, which acts as an irritant upon the tissues to which it is car But surely this theory of tuberculosis is inconsistent with the broad fac human pathology, whatever may be its application to the artificial tu culosis of animals. Nothing is more certain than that, in man, the in sated pus of a common abscess, or the caseous matter of an atheroma artery, or of a degenerating new growth or gumma, does *not* produce tu culosis. The few cases that have been recorded as illustrations of such occurrence serve, by their rarity, to tell against the conclusion they are tended to support. Thus Dr Murchison some years ago exhibited at Pathological Society a specimen in which a simple ulcer of the duode (an affection generally entirely free from all trace of caseation) had followed by tubercular disease in the lungs. Is there the smallest re for supposing that this was anything more than an accidental coincide Dr Hamilton insists upon a case in which a woman died, thirty-three after her delivery, of general miliary tuberculosis. She had been attac by a rigor on the seventh day, and her symptoms were at first mainly th of peritonitis. In many places, says Dr Hamilton, more especially bel the uterus, the peritonitic fibrinous effusion had become caseous, and and there softening had occurred. He assumes that this was the start point of the tuberculosis; but it seems to be very doubtful, according observations made by Cohnheim on the rate of development of acute tu culosis, whether it would have been possible for the process to have run course within twenty-five to twenty-six days, even supposing that the tu culous "ferment" became "elaborated" at the very moment when peritonitis first began. Moreover, there is no difficulty in supposing

man's illness was, from the first, acute tubercular peritonitis, forming, ften happens, the clinically obvious part of a more widely diffused tuberculosis. In fact, cases of acute tuberculosis in man, attributable ction from non-tubercular lesions, are so scarce that it is impossible to any significance to them.

antime, however, it has turned out that the experiments which were ed to prove that tuberculosis could be set up in animals by the tion of non-tuberculous matters had been misinterpreted. Klebs that in all probability they were vitiated either by the accidental ce of the specific poison of tubercle at the time when the operation rformed, or by the wound becoming infected with it afterwards. eim afterwards frankly acknowledged that, having repeated his inves- ns both at Kiel and at Breslau, he has utterly failed to obtain the same as before; and he became one of the warmest supporters of the nature of tubercle. On referring to Dr Wilson Fox's observations that all the animals which were inoculated by him, whether with lous or with non-tuberculous substances, were placed in a single so that it was quite possible for them to have infected one another tally.*

anheim made a further advance, by showing that in rabbits and in pigs tuberculosis has a tolerably definite period of incubation: from n to twenty-one days. When a minute fragment of tuberculous is introduced into the anterior chamber of a white rabbit's eye through sion in the cornea, the slight reaction which arises after the operation subsides, provided that the tubercle is perfectly fresh. The fragment w be seen through the transparent cornea, and it diminishes in size day until it may altogether vanish. Then, at the end of the period or three weeks, an eruption of small transparent grey granulations on the iris. Afterwards they caseate, and a destructive inflammation whole eyeball often results. Ultimately the animal may die of a miliary tuberculosis, in from five weeks to three months, or later; diffusion of tubercles may be limited to the lungs or to the peritoneal or, lastly, there may be no development of them in any organ outside eball.

complete the account of the experimental study of tuberculosis in the nimals, we must describe two sets of observations which illustrate ls by which the specific virus of tubercle may be supposed to invade man body.

The disease of cattle which is known in Germany as *Perlsucht*, England as "the grapes," is now generally admitted to be al with tuberculosis, although the morbid appearances, as seen by aked eye, differ considerably from those with which we are r in man. It is a chronic affection, which may run on for years without impairing the animal's health. In fact, milch cows almost the only instances in which symptoms appear during life: re chiefly cough and wasting. It appears that animals thus affected en sold to the butcher, so that besides the risk of drinking their milk the early part of their illness there is the further risk (at least to

t a meeting of the Pathological Society on December 4th, 1883, Dr Fox stated that equest the experiments referred to in the text had been recently repeated by Dr Williams. The details of this series of experiments were stated, with the precau- ainst accidental infection; the results were absolutely negative.

the poor) of eating the diseased tissues, perhaps concealed in uncook sausages. The frequency of Perlsucht may be judged from the fact that Augsburg 2 per cent. of all cattle slaughtered were proved to be tuberculo and of cows as many as 5 per cent. In Paris bovine tuberculosis l become less common of late (1889). Its experimental propagation in oth than bovine animals has been studied by Gerlach, Klebs, Orth, and othe Not only have pigs, lambs, rabbits, and guinea-pigs been successfully infect by the milk from diseased cows, but a like result has been attained feeding animals with portions of the affected tissues removed after the co were slaughtered, and also by inoculating them beneath the skin with su materials. Klebs found that even boiling the milk did not, in two expe ments, render it inert.*

A further step in the investigation has been taken by Bollinger, w thinks that a broad distinction can be drawn between the Herbivora a the Carnivora as regards their liability to be affected with tubercul through the alimentary canal; he supposes that flesh-eating animals secr a gastric juice which has a more active power of destroying the bacill Man, as an omnivorous creature, ought to occupy an intermediate positio

One is strongly tempted to find in these experiments an explanation the frequency of mesenteric disease in children, in whom milk forms important an article of diet. The following observation, recorded in 18 by Dr. W. H. Spencer, of Clifton, may perhaps bear upon this point. M than twenty boys in an industrial school fell ill of what was supposed to enteric fever. Most of them recovered, but four died; and in each fa case the organs were found to be full of tubercles. In every instance, ho ever, caseation of bronchial glands was present, which could scarcely ha occurred in the three or four weeks of the boys' illness.

(2) The other set of experiments was made by Tappeiner, in order determine whether tuberculosis could be induced in animals by the inha tion of the sputa of phthisical patients diffused in the air as a spray. I method was to employ six grammes of the sputa at a time, and the inha tions were continued for six hours a day during fourteen days in successi Dogs were used in this inquiry, and the earliest period at which tuberc

* Dr Creighton has recorded several cases in which he believes that *post-mor* appearances found in the human subject justify the conclusion that the disease was deri from the cow. His point of view, however, is that Perlsucht, or bovine tuberculosis not identical with the tuberculosis which chiefly occurs in man, and that it will hencefo be possible to separate by certain characters cases having such an origin from those wh may be regarded as proper to the human species, and he cites Gerlach as having sta that in some of the animals that were infected by him from the cow the "peculiarity Perlsucht was unmistakable." In addition to there being grey translucent tubercles, l those which are seen in man and in apes, the characters on which Dr Creighton relies the following:—The peritoneum and the pleura present round or oval nodules, of the s of lentils, sometimes pendulous, sometimes connected with one another by fibrous co sometimes flat and cohering together so as to resemble the duckweed on the surface of a po In the lungs there may be soft, whitish masses up to the size of a walnut, some rou others wedge-shaped and like infarctions. These organs may also have in their inter closed smooth-walled cavities, giving them somewhat the appearance of a crumpet. It is be observed that most of the cases in which Dr Creighton found such lesions occurred, in children, but in adults of all ages. Now the prospect of our being able in fut to distinguish from other cases of tuberculosis in man such as are of bovine orig does not seem to be promising. But even if what Dr Creighton terms the "stru tural mimicry of infection" really goes so far as to give special characters to bovine cas it yet would not follow that the two diseases are fundamentally distinct. Koch fou his bacillus in ten cases of Perlsucht, chiefly in the interior of giant-cells surroundi the calcified nodules in the lungs, but also in the bronchial and even in the mesente glands.

were found in the lungs after the commencement of the inhalations was on the twenty-third day. In no single instance were the results negative.

Bearing of the above experiments on human pathology.—If we now turn to consider the bearing of these experimental observations upon tuberculosis, as it is seen in the human subject, we shall be obliged to conclude that they are only applicable within narrow limits.

There are two questions to be discussed which must be carefully kept apart, although they are often confounded together. One concerns the ætiology of tubercular diseases, or invasion from without, the other refers to the way in which acute and chronic tubercular lesions spread through the patient's tissues, or infection within the body.

(*a*) *The origin of tuberculosis.*—The view that infection from without is the essential part of the ætiology of tubercular diseases is inconsistent with clinical observation. There is the clearest evidence that phthisis does not ordinarily spread from patients to other patients, or to relations, nurses, or medical men. On the other hand, it has been proved that its prevalence is greatly augmented by such conditions as overcrowding and defective ventilation, and also by exposure to cold and wet, and by dampness of soil. Overcrowding and defective ventilation may be supposed to act by lowering the general health. But it is difficult to see how exposure to cold and wet can induce the disease except by their liability to set up catarrhal affections of the pulmonary and bronchial tissues; probably this may also be the way in which dampness of soil acts. Moreover we shall find reason to believe that the affections of the lungs due to inhalation of dust are really tubercular, and not (as is generally taught) purely inflammatory. Again, hereditary transmission plays a most important part in the ætiology of phthisis.

It is not easy to frame a theory of the ætiology of tubercular diseases which shall accord with these facts. There are probably great differences in the *susceptibility* of different persons to the virus, or, perhaps more correctly speaking, in the *resistance* which they offer to it. Moreover, notwithstanding the enormous mortality from phthisis and the affections allied to it, this resistance must be far greater in the human subject than in the rabbit or in the guinea-pig; for one must remember that those who die of tubercular diseases have commonly lived for several years, during which time they have most likely been exposed to tubercular infection again and again. It is also necessary to admit that this resistance varies in the same individual at different periods, and that it is not absent even among those in whose families phthisis is hereditary. Otherwise we should find that when one member of such a family was attacked by the disease it would quickly spread to other members. Now, the fact is, that even if several brothers and sisters die in succession, their illnesses are usually separated by considerable intervals of time.

The greatest difficulty is to understand how an affection produced by the growth of a bacillus can bear any relation to causes which might be expected to set up a simple inflammatory process. One possible solution is that the microbe may be so widely diffused that it is continually finding access to the body, but fails to implant itself until the local resistance of the tissues happens to be lowered by inflammation. But this seems to be inconsistent with Koch's statement that the bacillus cannot grow unless the temperature is above 86° F. Cohnheim thought that the bacillus may remain latent in the body for an indefinite time until some accidental cir-

cumstance calls it forth into active growth. He even imagined that
hereditary transmission of phthisis means the direct transference of
tubercular virus, either in the spermatozoa or in the ovum, as virus
transmitted in the case of the *pébrine* of silkworms. There is perhaps
third possibility, namely, that under certain unknown conditions the occ
rence of what is at first a simple inflammatory process may cause mic
phytes already existing in the body to acquire infective properties that th
did not previously possess, and to convert the simple inflammation int
tuberculous one.

(*b*) *The spread of acute tuberculosis.*—Let us now pass on to consider
what extent the recent experimental observations upon tubercle thr
light upon the *mode of spreading of tuberculous lesions within the human bo*

Acute general miliary tuberculosis, with its myriads of minute cent
of tissue-irritation, is hardly explicable in any other way than by the
semination throughout the blood-stream of minute particles of the tubercu
virus in the form of bacilli or of their spores. Buhl himself failed to fin
caseous mass which, on his view, could have been the starting-point
general tuberculosis in no fewer than thirty out of three hundred cas
and this notwithstanding that he accepted as satisfactory such lesions a
small embolic plug in an organ, or a degenerating purulent exudation i
serous cavity. The probability now seems to be that the real starting-po
is often a very recent patch of tubercles which happens to be so situa
that an infection of the blood-stream is a necessary result of its presen
Thus, for instance, Weigert discovered, in many instances of acute tube
losis, a caseous mass of tubercle, growing into the interior of a pulmon
vein, by extension from the pleura, or the bronchial glands, or the med
tinum. In quoting this observation, Cohnheim alludes to Ponfick's case
tuberculous infiltration of the wall of the thoracic duct as another poss
source of blood infection : this, however, is a very rare lesion.

But it must not be supposed that the growth and the distribution
tubercles, when they are ever so widely scattered throughout the body,
regulated solely by the way in which the bacilli are disseminated thro
the blood-stream. There seems to be a curious difference between
artificial tuberculosis of animals and the disease as it is seen in men w
respect to the distribution of the tubercles. In the former affection they
found beneath the pleural surface more abundantly than in the substa
of the lung, and Dr Sanderson speaks of them as having sometimes the fo
of blunt cones. In both respects artificial tuberculosis resembles the
other great examples of tissue infection by the blood—pyæmia and malign
tumour. A third point of similarity between the three affections is that
all of them the liver forms a conspicuous seat of the secondary lesions.
artificial tuberculosis Dr Sanderson seems to have found tubercles in
liver more often than in the lungs, but Dr Wilson Fox observed li
difference between the two organs in this respect. On the other hand,
the general miliary tuberculosis of man the liver is much less frequently a
less obviously affected than the lung, although no doubt the microsc
shows that hepatic tubercles are far more often present than used to
supposed. In the lung itself the tubercles are not more numerous bene
the pleural surface than elsewhere, and they do not possess the conical
wedge-like form.

Further, in many if not in most cases of acute tuberculosis, the
tribution of tubercles in the lung is such as to show clearly that the p

clivities of the affected tissues play a part in determining it. In the upper lobe the tubercles are more abundant, larger, and more advanced in their development than in the lower lobe. They often gradually diminish both in number and in size from the apex downwards. They may be quite caseous above, grey and semi-transparent below. In other words, even when the virus is carried by the blood-stream to all parts of the lungs at once, the result is an affection which bears some resemblance to an ordinary local phthisis so far as concerns the distribution of the tubercles. This fact helps to explain what would be otherwise unintelligible—the frequent limitation of acute tuberculosis to a single organ or tissue. In tubercular meningitis, for example, it often happens that not a single tubercle exists anywhere except in the cerebro-spinal membranes; and yet one can hardly doubt that bacilli in immense numbers must have been distributed by the blood equally to all other parts of the body.*

(*c*) *The distribution of chronic tuberculosis.*—In chronic tubercular affections the mode of spreading seems to be by the gradual invasion of the lymph-channels from point to point. Among the most striking appearances are the lines of progressive thickening and caseation, with or without the formation of distinct tubercles, which run in the course of the sub-peritoneal lymphatics from the floors of intestinal ulcers. It does not often happen that the process of local infection fails to respect an anatomical boundary line between two widely different tissues; but in children the present writer recorded two or three cases in which a continuous cheesy mass, with a festooned growing border, extended from bronchial glands directly through the lung-substance, and one similar instance in an adult. A still more striking case seems to have been met with by Buhl. A child had caries, with caseation, of the lower dorsal vertebræ; the pleura became adherent, and the ulcerative process spread continuously into the base of the left lung. And Grancher ('Arch. de Phys.,' 1878) mentions a case of tubercular peritonitis, in which tubercles penetrated the diaphragm and infected the pleura covering the inferior surface of the lung, without adhesion having taken place. But in most instances of chronic tuberculosis the special proclivities of the several organs and tissues play a most important part in determining and in limiting the distribution of the tubercles. It is indeed difficult to see how the bacilli can fail to enter the blood-current in greater or less numbers in any of these cases; and if so, the resistance of the tissues in general can afford the only reason why lesions are not always found scattered irregularly through all parts of the body. Instead of this, the fact is, as the writer pointed out in the 'Pathological Transactions' for 1874, that several distinct varieties of chronic tuberculosis can be recognised, each of which has peculiarities of its own, in regard to the organs and tissues attacked. A parallel can generally be found for the distribution of each of these several varieties in the similar distribution of some other non-tuberculous disease; so that one is forcibly reminded of what Darwin calls the "correlated variation" of organs.

The following are the chief local varieties of chronic tuberculosis:

1. Pulmonary phthisis is very commonly accompanied by tuberculosis and ulceration of the air passages (especially of the larynx), and of the intestine (especially the lower end of the ileum). Some observers think that the affection of the lungs directly causes the lesions in question, the larynx being

* It is, however, possible that, in this very acute disease, infection is carried through the sub-arachnoid space by the movements of the cerebro-spinal fluid.

infected by the sputa which pass over it, and the ileum by the sputa w
are swallowed, and there is some experimental evidence in support of
view. But it is worthy of notice that, in enteric fever likewise, ulcer
of Peyer's patches and the solitary follicles occurs together with ulcer
over the bases of the arytænoid cartilages; and also that, in cases of
pneumonia, ulcers are apt to form at the same spots within the larynx.

2. Dr Wilks long ago pointed out that tubercle sometimes attack
pleura, the peritoneum, and the pericardium, without affecting any o
solid viscera. As already remarked (p. 60), the same distributio
observed in some cases of simple inflammation.

3. Tuberculous disease which began in one kidney not only spreads
extraordinary extent by continuity along the genito-urinary mucous memb
and the corresponding submucous tissue, but is also commonly attended
like affections of the opposite kidney, and (in the male) of one or both o
testes. If infection occurs by the blood-stream, tissue proclivities
surely play an important part in the result. Have we not an analogous
in the occurrence of a "sympathetic" orchitis in a case of renal calc
There is also a relation between tuberculous disease of the kidney and
disease of the lumbar vertebræ at the same level: but in this instance d
extension probably occurs.

4. Addison's disease of the adrenals (the tuberculous nature of
is well ascertained) is sometimes associated with spinal caries at
same level, which, indeed, probably precedes the adrenal lesion in poi
time. The writer saw two examples of a still more remarkable conne
between solitary tubercle of the brain and tubercle affecting the adrenals i
form of one or more scattered cheesy masses. Virchow taught that gliom
growths sometimes occur simultaneously in the brain and in the adrena

5. Tuberculous disease of the lymph-glands often spreads widely thr
out the body, and this not merely by obvious continuity, for it may
groups of glands widely distant from one another. It is also very gene
attended with tuberculosis of the spleen. A precisely similar associ
is seen in Hodgkin's disease.

6. Several of the joints are often affected by tuberculous disea
succession, without any corresponding affection of other structures.
again, one is reminded of the frequent limitation of pyæmia to joi
another illustration of the effect of local proclivities in determining
locality of lesions, even when they are due to infection of the blood.

It is still an open question whether multiple tuberculous affectio
the same subject are not sometimes independent of one another.
author was once much struck by finding in an infant, six months
two large masses of tubercular glands, entirely distinct from each other
in the chest, the other in the abdomen; and we not infrequently meet
cases in which the distribution of tubercular lesions seems to be capric
without any one of them being obviously of older date than the rest.
we have found phthisis associated with a tuberculous affection of one
and of the vesiculæ seminales in a man, and with a similar disease o
uterus and of one adrenal in a woman. In a child who died with a t
culous growth in the cerebellum there was a mass of caseous gland
the abdomen. Similar instances might be multiplied indefinitely. B
is possible that all, or any of them, may have been due to chance infecti
the blood-stream, the virus being carried to a spot where it met wit
resistance sufficient to check its action.

Historical retrospect.—It is interesting to ask whether any of the writers in the early part of this century expressed opinions approaching those which seem to accord best with our present state of knowledge. As regards the doctrine of the unity of phthisis, we need not look beyond Laennec. But his conceptions as to the relation between that disease and inflammation may almost be summed up in the statement that inflammation might occasionally be excited by the irritation caused by a numerous crop of tubercles. Nor can we assign a large share of credit to Reinhardt. It is true that, in 1850, he identified grey tubercle and grey infiltration with inflammatory processes, but, on the other hand, he maintained that yellow or cheesy tuberculous matter never arose out of the grey, but was merely inspissated pus. Among English physicians, Thomas Addison taught that inflammation constitutes the great instrument of destruction in every form of phthisis, or, as he put it in 1841, that pneumonic phthisis and inflammatory tubercle are identical (Addison's works, pp. 40, 64). Prof. Alison, of Edinburgh, in his 'Outlines of Pathology,' published in 1844, stated that "in certain constitutions, tubercles and all their consequences are direct effects of inflammatory action." Dr C. J. B. Williams classified grey and yellow tubercles as cacoplastic and aplastic varieties of coagulable lymph, "differing from the normal plasma, not in kind, but in degree of vitality and capacity of organisation."

At present we should best perhaps put the case thus. Tuberculosis is a general infectious disease, derived, as a rule, but perhaps not invariably, from one or more local caseous masses the product of inflammation. The primary and the secondary products are both inflammatory, of the kind described as *granuloma* (p. 60), and both constantly contain a specific bacillus, which may be reasonably regarded as the contagium vivum to which the morbid process is due. But besides the granuloma-growth there is also ordinary secondary inflammation, purulent, ulcerative or fibroid, which in most cases follows as a complication.

AGUE*

Ye ben full cholerik of complexion;
Beware the sunne in his ascension
Ne find you not replete in humours hote;
An if he do, I dare well lay a grote,
That ye shall have a fever tercian,
Or an ague that may be your bane.

CHAUCER.

Intermittent Fever—Its pathology, history, and distribution—Incubation—cold, hot, and sweating stages—Regular and irregular varieties—Rem Fever—Malarial cachexia—The spleen, liver, and other organs in ag Melanæmia—Nature and laws of malarious contagion—Microphytes Microzoa—Diagnosis—Treatment.

WE have now to discuss a disease which differs from the specific fe in some important respects. In its most typical forms its course is i rupted by definite intervals of apyrexia, so that, instead of appearing continuous fever, it consists of a succession of independent paroxysm "fits," which recur with marvellous regularity. For such cases the nam *intermittent fever* is commonly employed. But they cannot be separ from others which are due to the same cause, although the subsidenc the pyrexia is only partial, so that they are said to be examples of *rem fever*. The English term "Ague" includes both of these as well as sub nate varieties.

The poison which excites ague has long been known as *malaria* (*i. e.* air). It enters the human body from without; but, unlike the virus of other specific diseases, it never passes directly from one person to anot In other words, ague, though in a broad sense one of the "infective" dise is not "contagious," nor even "infectious" in the narrow sense in which epithet is generally employed. Vaccinia and Syphilis are contagious person to person, *i. e.* inoculable by direct contact, but not infectious, *i. e* conveyed to persons at a distance. Typhus and Measles are contagious infectious, *i. e.* conveyed from person to person by direct contact and distance. Cholera probably, and Enterica almost certainly, is not conv through the air, nor yet by direct contact, but only by means of a viru contagium which is developed after its discharge from the body. Ague is conveyed from person to person at all, but from a place, probably from or water, to persons. According to the bacterial theory of specific disease proved in a few instances, more or less probable in several, and without evidence but analogy in the rest (cf. *supra*, pp. 12, 13)—the microphyt Vaccinia and Syphilis can only be transferred by direct inoculation into blood or lymph; that of Typhus, Plague, or Scarlatina, can be carried by air or on fomites, and introduced through the stomata of the air-vesicles

* *Synonyms.*—Intermittent Fever, Periodic, Malarial, Miasmatic, Paludal or M Fever.—*Fr.* Fièvre intermittente, palustre, paludéene; *Germ.* Wechselfieber, Sumpffi The English word "Ague" is derived from Fièvre aigue, *Febris acuta.*

the lymphatics by means of the inspired air; that of Enteric Fever is harmless when first discharged, but after certain stages of growth outside the body of the host may enter the alimentary canal, and there reproduce its kind, like the ovum of a tapeworm or a trichina; and, lastly, the microphyte of Ague is not solely parasitic, but lives and grows outside the body, and possibly, like many parasitic worms, can only complete its cycle of development when it is at one stage parasitic and at another free.

Descriptions of the different varieties of ague are to be found in the writings of Celsus and other ancient writers; for various forms of intermittent fever were, and still are, the commonest disease in Greece and Italy. The first observer who took a clear view of malaria, as a noxious effluvium given off by marshes, appears to have been Lancisi, in a work published at Geneva in 1716.

Down to a very recent period intermittent fevers were common over the greater part of England, particularly in London and in the counties of Lincoln, Cambridge, Essex, and Kent. Drainage has much limited the extent and severity of the disease, but it is still met with along the banks of the Thames, and we see more or less marked cases of malarial cachexia among our out-patients from Southwark, Rotherhithe, and Deptford.

The *geographical distribution* of malarial disorders has, however, so important a bearing on their ætiology that it is best deferred till later.

It is a curious fact that malaria appears to be almost without influence upon domestic *animals*, at least in those countries where its effects have been most studied. In Italy, however, a few instances have been recorded in which horses or oxen have had intermittent attacks of fever, or have suffered from cachexia attended with enlargement of the spleen.

Incubation.—As a rule, those who are attacked by ague have lived for a time in a malarious region, and seem to succumb to repeated doses of the poison, rather than to take the disease on any particular occasion. When a single exposure has taken place, an interval of from six to twenty days generally elapses before the paroxysms begin. Dr Maclean, however, in 'Reynolds' System,' mentions the case of three German missionaries, fresh from Europe, who passed a night with an English officer in an unhealthy spot, at the foot of the Segoor Pass in India; next morning they pursued their journey, but within less than twenty-four hours three out of four of the party were stricken with fever. And Hertz, of Amsterdam, writing on this subject in 'Ziemssen's Cyclopædia,' declares that on several occasions, having purposely placed himself in a marshy ditch at a time when it was drying up, he has been attacked within half an hour by giddiness, shivering, nausea, and other symptoms, which ended in a slight paroxysm of fever a few hours afterwards. On the other hand, it is well known that the onset of the disease may be much longer delayed. Sailors have fallen ill upon the open sea, weeks or months after leaving a port infected with malaria. In London the Irish poor often apply for hospital relief in the spring, on account of ague which, although only just declared, must have been contracted during their autumnal migrations into Kent for hop-picking.

Premonitory symptoms.—Among strangers who have recently entered a malarial district, the occurrence of a regular paroxysm is in most cases the earliest symptom of ague. But, according to Hertz, when the patient has been living for a long time in the same place, a prodromal stage may sometimes be observed. It lasts a week or more, and consists of vague

malaise, fatigue, headache, and pains in the limbs, in association with nau
loss of appetite, and other symptoms of disordered digestion. There may
be occasional sensations of chilliness, alternating with slight flushes of h

The attack.—The ague-fit itself is divided into three periods, which h
long been known as the "cold," the "hot," and the "sweating" stages.

1. The *cold* stage begins with the patient's feeling tired, weak,
listless. He yawns and stretches out his limbs. He complains of an
comfortable sensation at the epigastrium, of headache, or of giddin
Before long, these symptoms merge into those of shivering or *rigor*.
experiences a chilly feeling along the spine, which quickly spreads all
him. He shudders, his teeth chatter, his knees knock together, his wh
frame may be so violently agitated that the bed into which he has c
shakes beneath him. His voice is feeble and his speech is interrupted
the quivering of his lips. At the same time his appearance undergo
remarkable change. He grows pale, his features shrink, his ears and
and finger-tips turn livid, his skin becomes dry and rough—*cutis anserin*
"goose-skin." Yet the thermometer, as De Haen discovered more th
century ago, shows that in the central parts of the body the temperatu
not lowered, but raised several degrees above normal. It must not, howe
be supposed that the patient's sensations deceive him as to the conditio
the surface, and especially of the more distal regions. One has only to
his nose or his fingers in order to assure oneself of the fact that they
really cold; and a surface-thermometer, or an ordinary thermometer hel
the patient's hand, will remain far below the natural standard, while in
axilla, the mouth, or the rectum it shows marked pyrexia. The tempera
begins to rise before any symptom of the onset of the ague-fit is experie
by the patient. At first its increase is gradual, but with the develop
of the rigor it makes a sudden leap upwards, perhaps passing through
or five degrees Fahrenheit in the course of an hour.

The patient during this stage feels dry and parched; his tongu
white; he often complains of nausea, and sometimes vomits. His pul
quick and small, and may be irregular. His respiration is short, hurr
and distressed. His urine, although pale, is often very irritating, so
Maclean has found it desirable to administer bicarbonate of potass
even tincture of opium for the relief of this symptom alone. Wa
spoke of the urine as scanty, although passed frequently; but the car
measurements and analyses of Redtenbacher and of Ringer have shown
it is in reality considerably increased in quantity, when compared with
amount passed each hour during the apyretic interval, and that there is
a marked increase of the urea and chloride of sodium. The excess, b
of the water and of these solid constituents, not only lasts throughout
whole length of the fit, but begins before the patient feels chilly.

2. The *hot* stage gradually succeeds. The patient ceases to shiver,
begins to experience flushes of heat about the face and neck, which prese
diffuse themselves over his body. But for a time, if he attempts
throw off the bedclothes he has piled over him, slight rigors reapp
At length, however, even the extremities become hot and glowing.
aspect is now again altered. His face is flushed, his eyes are injected,
skin becomes smooth and turgid. The temperature, as measured by
thermometer, still continues to rise for some time, and reaches 104°, so
times 106·5°, or even higher. The surface of his body, even of the di

parts, now feels pungently hot to the hand. Evidently, there is not only an increased generation of heat, but it is now freely carried to the periphery, and abundantly dissipated. The pulse is not only rapid, but full and throbbing; and the breathing is deep as well as frequent. The patient complains more than ever of headache, which is now of a throbbing character; and he is exceedingly restless and uncomfortable. The urine during this period is described as differing in appearance from that of the cold stage, being now high coloured and concentrated; and both Watson and Hertz speak of it as passed in but small quantity. There is often an eruption of herpetic vesicles upon the lips, or the nose, or the tongue.

Albumen in the urine, accompanied by casts and even by blood, has been observed by Griesinger and Hertz, but this is a very rare complication.

3. The *sweating* stage follows in its turn. The surface gradually becomes soft; then a little moisture breaks out upon the forehead and the face, and before long the whole skin is bathed in the most copious perspiration, which saturates the patient's linen and bedclothes. It is said that the thermometer sometimes continues to rise for a little while, so that the maximum temperature may occur during this, and not during the hot stage; but, as a rule, the pyrexia begins to decline from the moment when the skin ceases to be dry. The fall is at first slow, but after half an hour or an hour it becomes more rapid, and goes on until the normal temperature is reached. According to Wunderlich, this takes place by a series of steps, there being a drop of from one fifth to one third of a degree Fahr. about every fifteen to thirty minutes. All observers speak of the urine during this period as differing from that passed in the previous stages in showing a thick deposit of lithates. The breaking-out of perspiration is attended with complete relief to the patient; he loses his pains, the throbbing of his arteries ceases, he is no longer tormented with thirst, and his tongue becomes moist. After a time he perhaps falls asleep; and, when he wakes, he feels perfectly well, except that he may be somewhat exhausted.

Recurrence.—The subsidence of the ague-fit or paroxysm by no means brings the disease to an end. As we have already stated, its most remarkable feature is that precisely similar attacks are repeated again and again, recurring at perfectly definite intervals. Some patients have a fit every day; the ague is then said to be *quotidian*. In other cases it occurs every other day; and this form of intermittent fever is styled *tertian*, for according to the Latin way of counting it falls on every third day, or as we should say on every other day. If there are two entire days between the paroxysms, the disease is a *quartan* ague. In other words, an interval of about twenty-four hours characterises a quotidian, one of forty-eight hours a tertian, and one of seventy-two hours a quartan. Nor does this exhaust all the possible varieties. In some cases in which there is an attack every day, each paroxysm differs in severity or duration or in the hour of its occurrence from that of the preceding day, and exactly resembles that which occurred two days before. Thus a tertian type is clearly perceptible, and the affection is then called a *double tertian*. So, again, it is possible to have a *double*, or even a *treble quartan* ague. Or a patient may have two ague-fits one day, and a single fit on the following day, this series being regularly repeated; and one may then suppose that a quotidian and a tertian are combined. Such a case constitutes the ἡμιτριτᾶιος of Celsus, or, as subsequent Latin writers termed it, a *semitertian*.

The return of the paroxysms of ague is often so regular that it can foretold with absolute certainty; but even then the hour at which the begin is not always the same on each occasion. Sometimes it is earlier, e time by a constant difference; sometimes it is later. In the former case, disease is said to *anticipate;* in the latter case to *postpone.* Whereas one is a sign that the severity of the case is on the increase, the other i cates that it is becoming milder. Such variations may even bring abou change of type; thus an anticipating tertian may at last pass into a quotid and a postponing quotidian may be gradually converted into a tertian. So times the attacks of a quotidian fever are so prolonged that before the sw ing stage of one fit is over the cold stage of the next one begins; the dis is then said to be *subintrant.*

With regard to the relative severity of the three principal forms of a writers state that quartans are peculiarly obstinate.* This variety, whic comparatively rare, is most apt to occur in the autumn; and it has l been well known that autumnal agues are worse than those contracted the spring.† Hertz states that in the tropics the disease never assumes quartan type; and yet ague is certainly more severe there than in the t perate zone. In hot countries the quotidian appears to be the most comm form of ague, whereas in temperate climates the tertian is more frequen

There are some other differences in the course of the several varieties intermittent fever. Thus the fits of a quotidian are said generally to se during the morning, those of a tertian at about noon, those of a quartan later in the day. It is stated that the average duration of a paroxysm quotidian ague is from ten to twelve hours, that of a tertian from six to e hours, that of a quartan from four to six hours, but that in the last-na variety the cold stage is more prolonged than in the others.

Subsequent course.—Intermittent fever appears to be never directly fa Its duration is very variable. Sometimes, even though the patient rem in the place where he acquired it, it ceases after a few paroxysms. In o cases it comes to an end when a change of season reduces the malaria state of inactivity. In others, again, ague recurs for an indefinitely l period, until the victim is compelled to remove to some other dist There is always a strong tendency to relapse, not only under a fr exposure to the ague poison, but even without it; and it is a remarka fact that, whether the type be tertian or quartan, the paroxysms o relapse often occur on those very days on which they would have been if the disease had gone on without break from the first. Graves has rela an instance of quartan ague which he watched for twenty-seven months, in which the periodic rate was maintained through thirteen out of sixt intervals, some of which lasted more than two months. A similar obser tion had previously been made by Dr James Gregory in the case of a relati who had marked on an almanac the days on which the fits of a tertian a might be expected to recur, and who found that for a long while they so whenever the east wind blew. Since the introduction of the therm meter into clinical practice, however, it has been shown that there is so times a distinct rise of temperature at the proper time for the paroxy although the patient himself may be altogether unconscious that anything

* Nevertheless the Latin couplet runs:

Pro febre quartana
Rara sonat campana.

† "An Ague in the spring is Physick for a King." Yet James I died of a tertian fe in March.

the matter with him. Ringer states that in spite of the absence of all febrile disturbance the periodicity of the disease may be indicated by the voiding of urine undue in quantity, and containing an excess of urea.

Varieties.—Ague-fits are not always characterised by the whole series of phenomena described above. Sometimes the cold stage is absent, sometimes the sweating stage. It is said that sometimes the usual order is reversed, as in a case cited by Watson from Maugenet. The patient in question was always first attacked with profuse sweating; then he became dry and hot; finally he felt cold and had distinct rigors.*

In certain exceptional cases the paroxysms differ altogether from those which are ordinarily seen, and they may be attended with great danger to the patient's life, so that both Trousseau and Hertz classify them apart. The strangest form is that which has been termed *syncopal*, in which there is a condition of suspended animation, so that the patient runs a great risk of being buried alive. Trousseau relates two instances of this. One occurred in a station-master on the Avignon Railway. He had been subject for some time to paroxysms of intermittent fever, and had repeated fainting fits; once he became pulseless, was supposed to be dead, and was carried to the mortuary. After some hours a servant happened to enter the place, and found him groaning; he was therefore taken back to his bed, and under large doses of cinchona he regained his health. It is singular that Dr Chauffard, the physician who observed this case, also met with another one of the same kind. A man had fallen into a faint, was taken for dead, and his face was covered with a sheet; Dr Chauffard, however, detected slight movements of his heart, although the radial, axillary, and carotid arteries had ceased to beat; he immediately administered a quinine enema, and the man was saved.

Scarcely less remarkable is another variety, which is attended with *coma*. Hertz says that instances of it were from time to time sent into the hospital under his care for apoplexy, and Graves placed on record a case in which he made this mistake. A gentleman awoke at about 4 a.m. with sensations of malaise, chilliness, nausea, and headache. After an hour he became extremely hot, the pain in the head was intense, and he passed from a drowsy condition into one of complete coma, with deep snoring, so that he "appeared to be labouring under a severe apoplectic fit." He seemed to derive much advantage from bleeding and other remedies, and in the evening he was perfectly well. The day but one after the same symptoms returned, and were removed by the same treatment; but when a third attack came on Graves saw that it was an example of *tertiana soporosa*, and cut it short by large doses of quinine.

In other cases it is said that epileptiform convulsions or tetanic spasms have been present, or that the symptoms have simulated those of hydrophobia. It even seems that the paroxysms of ague may imitate various abdominal or thoracic diseases—cholera, dysentery, peritonitis, pneumonia, pleurisy, are among those enumerated by writers. Hertz tells us of a man who was attacked at two o'clock in the morning with shivering and pain in the left side; at eight there was a distinct pleural friction sound, but twenty-four hours later he was perfectly well. However, on the following night, at twelve o'clock, all the symptoms returned, and by nine the friction sound was more evident than before; at four in the afternoon he was sweating and

* "'Tis but an ague that's reversed,
Whose hot fit takes the patient first."—*Hudibras*, part iii, canto i, 653.

free from pain; full doses of quinine were therefore prescribed, and he no further attacks.

With regard to these cases, and also to those of malarial syncope coma, we must be cautious in accepting them as mere varieties of ague it is an established fact that in districts where ague prevails all kin diseases assume a more or less distinctly intermittent character.

The same hesitation seems to be necessary before deciding the natu what have been termed *masked agues*, in which the paroxysms are state be of the most diverse descriptions, and attended with scarcely any fe disturbance, or even with none at all. The most important of these is ralgia, occurring especially in the region supplied by the first division o fifth nerve (and thus often called "brow-ague"), but sometimes assumin sorts of other forms. Not only have cases of sciatica and of other neur affections of the limbs been attributed to ague, but the same view has taken of painful affections of the mammary gland or of the testicle, and of alarming seizures attributed to cardialgia or to neuralgia of the vagi it is hard to say what evidence in favour of such interpretation wou conclusive. Obviously it is not enough to show that the attacks recur a certain degree of regularity, and pass off under the influence of quinin as much as this may be said of almost every kind of neuralgia. Th servance of a tertian or quartan type would no doubt be very significant Hertz says that masked agues are usually quotidian. It must be bor mind that the more extensive a man's experience in regard to intermi fevers, the more likely is he to be led astray by tradition, or by per bias, until he has recourse to the same convenient hypothesis for the sol of every obscure and indeterminate affection, such as occur frequently en in clinical practice in districts where no ague is met with. What, for exa is to be said of the case of Dr Macmichael, cited by Sir Thomas Wa who "caught an ague many years before his death by sleeping on a somewhere in Greece, and was ever after subject to occasional attac periodic headache and other aguish symptoms, for which he was oblig have recourse to bark or arsenic"? And what value can be assign Trousseau's statement that there are cases in which insomnia, unaccomp by fever and not preceded by rigors, recurs every two or three nights these cases are of the nature of masked ague, and that they are cur similar treatment?

Remittent fever.—Malaria is not limited in its effects to the producti the different forms of intermittent fevers. In hot countries, and d the hot seasons of the year, even in temperate climates, it causes f which are either continuous or interrupted only by *remissions*, interv which, instead of there being complete apyrexia, there is only a p lowering of the temperature and of the pulse, with some degrees of a ment of the other symptoms. For cases of this kind the technical na *remittent fever*, but in India a common term for them is *jungle feve* another is *bilious remittent fever*. They are, in fact, characterised by a of phenomena which do not belong to the milder effects of the marsh p as well as by the absence of some of the more distinctive features of ord ague. Thus the cold stage is slight and ill-defined, and the hot sta followed by little or no sweating. The remissions themselves, which begin about midnight or in the morning, and which last for twelve or longer, may be so slight as to require careful clinical observation for

detection. A feeling of oppression at the epigastrium is present from the commencement of the patient's illness, and vomiting is usually a marked symptom throughout its course. The vomited matters may at first consist of food, but afterwards a watery fluid is ejected, often in surprising quantity, and it may ultimately become greenish-yellow, brown, or even in rare cases black. Headache is generally a prominent symptom, but not delirium.

In the worst cases, in which the disease is said to be of an "adynamic" character, the patient rapidly becomes very prostrate and insensible, his skin is yellowish and covered with petechiæ, his tongue is black, his teeth are covered with sordes, and hæmorrhages may occur from the nose, the mouth, and the limbs; or hæmaturia may be a prominent symptom. French writers have described such cases under the title *fièvre bilieuse hématurique.* Maclean, from whose description of remittent fever in 'Reynolds' System' most of these details are taken, says that except in such cases the urine seldom contains albumen; it is often abundant, and sometimes pale.

The duration of remittent fever is said to be generally from five to fourteen days. Even its worst forms ought, according to Maclean, to do well in most cases, if seen early and skilfully treated. Sometimes it ends with a critical perspiration, sometimes it subsides gradually, sometimes it passes into one of the regular types of intermittent fever. Death seldom occurs before the seventh or the eighth day, a point which may distinguish this disease from yellow fever in countries where they both prevail.

Typho-malarial fever is a name used in the United States for cases which are probably not a separate form of disease, but enteric or other specific fevers occurring in persons subject to malaria. See Dr Johnson's paper ('Trans. Assoc. of American Phys.,' p. 40).

Malarial cachexia.—In persons who have suffered from protracted ague, or who have had repeated relapses, a chronic condition of ill-health is apt to develop itself which is known as malarial cachexia. A precisely similar condition is not infrequently seen in those who have lived for a long time where the disease is prevalent, even though they may have never had any febrile symptoms. One of its most characteristic signs is a peculiar earthy sallow complexion; another is a damp, clammy state of the skin, especially noticeable in the hands. The patient is depressed in spirits, and wakes unrefreshed by the night's sleep; he often suffers from giddiness, noises in the ears, tingling in the hands and feet, pains in the lower part of the back, palpitation, loss of appetite, a furred tongue, and digestive disorders.

In all cases of this kind enlargement of the *spleen* can be made out on percussion. Very often the organ is to be felt beneath the left costal cartilages, extending down to the umbilicus or even lower. Sometimes it forms a conspicuous tumour, which used to be called an "ague-cake." Although in some very rapidly fatal forms of malarial fever the spleen has been found of unusual size, the rule appears to be that it only swells with every paroxysm of the disease, and subsides more or less completely during the intervals. It is generally supposed that the yielding capsule of this viscus allows it to become the receptacle of an undue proportion of the blood which is driven inwards from the surface of the body in the cold stage.

In cases of death from malarious cachexia the state of the *spleen* is found to be very different under different circumstances. In acute cases it is soft or diffluent, and during life it may rupture from the slightest accident, pour

blood into the peritoneal cavity and bring the case directly to a fatal is Hertz states that embolic masses are sometimes formed in it, which may to suppuration, or to gangrene, followed by intense peritonitis. On the o hand, in cases of chronic ague or of malarial cachexia, the spleen becomes tremely indurated. Not only is its hardness discoverable by palpation du life, but after death it is found to have little or no pulp, while the fibrous ments of its substance have undergone an immense increase. Its capsule is o very much thickened, and it may be fixed by adhesions to adjacent part

The *liver* is often found enlarged and indurated, and there appear be some doubt whether it may not undergo a change identical with cirrh Clinically this condition is further indicated by the presence of pain tenderness in the hypochondriac regions, and by the occurrence of a ascites with which œdema of the legs may be associated.

Maclean cites Parkes as having observed chronic Bright's disease those who had suffered from ague, and confirms the statement from own experience. But can one be sure that sufficient care was take eliminate other possible causes?

There is, however, another and altogether peculiar result of sever protracted ague. It is called *melanæmia*, and consists in the presence brown or black pigment, partly free, partly enclosed in leucocytes, whic found not only circulating in the blood, but also lying in the substanc the solid tissues. The pigment in question is no doubt derived from colouring matter of the blood. Klebs states that it yields Prussian when tested with ferrocyanide of potassium, so that it must contain which no longer forms part of an organic compound. It occurs either minute granules or in larger masses, irregular in shape, and sometimes a crystalline in appearance. Where there is a large quantity of it, the org are conspicuously discoloured. Thus the liver, the spleen and the kidn assume a slaty-grey colour, the medulla of bones becomes chocolate-bro and the cortex of the brain may appear as if rubbed over with blacklead

A most striking example of pigmentation of the brain, no doubt mala in origin, occurred at Guy's Hospital in 1829 in the practice of Dr Bri who figured it in his 'Medical Reports.' The case was that of a man w with his wife, died of severe fever immediately after they had walked up London from Horncastle in Lincolnshire. In Germany, as in Engla melanæmia with abundant pigmentation of the organs appears to be very ra all the well-known cases recorded by Frerichs belonged to an epidemic of a which arose in Silesia after an inundation in 1854. But more than observer has stated that he has constantly been able to detect pigment the blood, by microscopical examination, in cases of "pernicious" ague, of malarial cachexia. In 1877 Dr Stephen Mackenzie made a similar ob vation several times in the case of a man who had brought ague with h from India. The red discs were normal; but many leucocytes contai granules which were arranged round their nuclei, or sometimes complet filled them so as to give them a uniform brown or black colour. Af treatment with quinine, the melanæmia was no longer discoverable. T blood of the portal vein has been said to be specially affected with t change; Dr Hammond has even punctured the spleen during life, and dra off a few drops of blood from it for examination. The pigment is genera supposed to be originally formed in the spleen, and to pass from t organ into the blood, so as to be carried all over the body. It often blo up the capillaries, but it is also found in the walls of larger blood-vessels, a

even outside them in their sheaths. These facts do not prove that it may not have come from elsewhere, for wandering leucocytes may have carried it with them; but many pathologists think that, in some cases at least, it is developed *in situ* from extravasated red corpuscles. Whether melanæmia directly gives rise to any symptoms appears to be doubtful. Dr Mackenzie's patient had hæmorrhages into each retina, and the same thing has been observed in some other cases of ague. It is natural to suggest that they might have resulted from plugging of minute vessels with pigment, but the anæmia which is so commonly present in such patients would equally account for them. In 1880 a man who had caught ague in the Black Sea was in Guy's Hospital; he had a large hæmorrhage in one retina; but no pigment could be found in the blood. Capillary hæmorrhages in the brain have been attributed to pigmentary embolism of this organ; and a variety of cerebral symptoms have been supposed to result; but Hertz asserts that there is, in individual cases, no close correspondence between the occurrence of such symptoms and the demonstrable presence of the pigment in the minute vessels of the brain. Perhaps the most interesting question of all is whether there may not be something in common between melanæmia and that remarkable affection, paroxysmal hæmoglobinuria.

Ætiology.—We have now to consider what is the nature of the *malaria* or exciting cause of ague, under what conditions it is developed, and how it gains access to the human body.

That ague is apt to prevail in marshy districts is universally admitted. Yet it is no less certain that something more is needed than mere saturation of the soil with water. For countries like Ireland, which are widely covered with peat bogs, scarcely breed malaria; nor, according to Parkes, are salt marshes infested with ague, when they are regularly overflowed by the tide; and this, notwithstanding that for a large part of each day their surface is exposed. Again, the most virulent forms of ague have sometimes been seen in dry and barren districts. Such, according to Hirsch, are the table-land of Castile, the plain of the Araxes, and the lofty plateaus of Northern India and Persia, all of which are highly aguish; he even says that careful inquiry has proved that the malarial regions of Italy are in large parts of their extent devoid of water and sterile. Again, instances in which British troops have been attacked with the disease while encamped upon dry sandy soils, both in Holland and in Spain, are cited by Watson from observations made by Dr William Ferguson nearly a century ago; and Maclean lays stress upon the development of malaria in Hong Kong and in other places, situated upon granite rocks which are undergoing disintegration. These exceptional cases are fatal to a hypothesis which at one time was generally upheld, namely, that the poison of ague is nothing more than a product of putrefying vegetable matters. But there is no real difficulty in bringing them into harmony with cases in which the disease is developed in marshes, or along the estuaries of rivers. For accurate investigations have shown that even there the malaria is developed, not in the wet part of the year, when the ground is flooded with water, but rather during those seasons at which large parts of it are exposed to the air, and become more or less dry. And as Maclean has pointed out, it is tolerably certain that, in every instance supposed to be of an opposite kind, water might very easily have been present, either in the form of subterranean streams, or upheld by a bed of clay or other impermeable material, or only

saturating the soil up to a certain level. So again, it has been noticed
in Italy an occasional overflowing of fresh-water marshes by the sea
been followed by a great development of malaria; but this is not incon
tent with the fact that marshes which are always saturated with salt w
are healthy, since the conditions in the two cases are clearly different.

One way in which a hot sun probably favours the development of a
is by cracking the dry surface of the ground and allowing emanations
escape from the moist layers beneath. Again, it has repeatedly been fo
that the disease has reappeared in places that had long been free from
when the soil has been extensively disturbed for building purposes,
during the construction of canals or of fortifications. Conversely, much ca
done towards preventing the exhalation of malaria by draining the gro
and spreading a layer of fresh soil over its surface, or, in the case of villa
or towns, by paving the streets and courts.

Many districts are decidedly damp without being aguish; but
merely proves that other conditions besides a wet state of the soil
necessary for the production of malaria.

At certain times intermittent fevers spread to regions which lie far bey
their usual limits, and assume somewhat of an *epidemic* character. The y
1558, 1678–79, 1718–22, 1807–12, 1824–27, 1845–48 are mentioned
Hertz as having been characterised by such a wide diffusion of a
Watson says that he never knew ague widely prevalent in London exc
in 1827. From 1866 to 1868 there was an epidemic in Mauritius, altho
the island had previously been so free from malaria that the sufferers f
Indian fevers resorted thither. In 1869 it broke out for the first time
Réunion.

Climatic conditions.—With regard to the nature of other conditi
which favour the development of the ague-poison, very little is known.
is curious that there has often been an antecedent or simultaneous epide
of influenza, of typhus, cholera, or the plague.

One important condition is undoubtedly a high temperature. A
prevails with far greater intensity in the tropics than in temperate clima
while towards the poles it is unknown: its boundaries are about 63°
and 57° S. of the equator. Hirsch has endeavoured, upon very defect
data, to determine the corresponding limits of temperature, and finds t
mean summer temperatures rather than mean annual temperatures must
taken into account. In this hemisphere, he finds the highest range
malaria toward the North at a line between the isothermal lines of 60°
61° Fahr. Again, in particular districts, the occurrence of malarial fe
is governed in a very marked manner by variations of temperature. Dur
the winter they disappear entirely; and, other things being equal, they
always more severe in proportion as the season happens to be a hot o
In the tropics the exact period of the year at which ague is most preval
varies in different localities; generally speaking, it closely follows the ra
season. Hertz lays down the rule that, in order to escape malaria, o
should arrive in the East Indies between November and January, in t
West Indies between January and March.

In temperate climates malaria is usually more active in the spring a
autumn than in the height of summer. Wenzel made the important obs
vation that among the men employed upon the works at Wilhelmshafen t
development of ague followed the summer heat by an interval of twenty
twenty-five days, of which he supposed from six to eleven days to be occupi

by the generation of the poison in the soil, while the remaining fourteen days are the period of its incubation in the persons infected.

The liability to ague is greater near the sea-level than in cooler places higher up; but Parkes mentions some instances in which marshes at elevations of five thousand to six thousand feet have, in hot countries, been found to give off malaria. It is, of course, quite a different question to determine what is the lowest point on the hills above a marsh at which one may reasonably expect immunity from the disease. The fact is well ascertained that the wind sometimes carries the ague-poison to considerable distances from its source, not only on level ground, but also up the slope of a range of mountains. Parkes says that in temperate climates an elevation of at least five hundred feet above a malarial spot should be reached in order to escape its influence; in the tropics, one of a thousand to fifteen hundred feet, or even higher still. On the other hand, at the level of a marsh itself, the injurious emanations seem to have but little tendency to rise and diffuse themselves in the air. There is evidence that, both in barracks and in private houses, persons sleeping on the ground-floor are more apt to be attacked than those who occupy upper stories.

It is at night, and for a short time after sunrise, that malaria is most to be feared; probably the poison is harboured by the stagnant mists which are so apt to lie over the surface of damp ground until sunrise.

The presence of actively-growing vegetation appears to be adverse to the development of malaria; and there is reason to believe that the inhabitants of houses in the neighbourhood of a marsh are sometimes protected by the interposition of a belt of trees. The Eucalyptus is believed to be particularly useful in this respect. The poison also seems to be incapable of traversing a surface of water without undergoing absorption. When English troops occupied Walcheren and other parts of Holland, it was repeatedly noticed that only the soldiers who disembarked were attacked by ague; those who remained on board ship, even in narrow channels, escaped.

Chorography.—In England the chief seats of ague are along the eastern coast; Romney Marsh in Kent, the estuary of the Thames in Kent and Essex, the fens of Cambridgeshire and Lincolnshire, and the marshy lands of the East Riding of Yorkshire. In all these districts the disease has become far less frequent than formerly, since population has increased and improved drainage has brought more and more land under cultivation. Not many years ago cases were common in London. James I and Oliver Cromwell * died of ague contracted in this city. At present its occurrence is altogether exceptional, even in the low-lying parts of Southwark. In Scotland there is now but little malaria, and it is said to have begun to disappear before any drainage works were carried out. On the continent of Europe the regions in which the ague-poison is most prevalent are the following: the great plain of North Germany, with some of the Baltic provinces of Russia; Holland, with the adjacent parts of Germany and Belgium; the south-western departments of France; the western side of Spain and Portugal; almost the whole west coast of Italy; a great part of Greece and Turkey; the plains of Hungary; and the shores of the Black and of the Caspian Seas.

* 'The Court and Character of K. James,' by Sir A[nthony] W[eldon], 1651, p. 160. Dr Bates gives the following account of the spleen at the autopsy of the Protector:—"In naturalibus fons mali comparuit; lieue, licet ad conspectum sano, intus tamen tabe instar saurcæ referto." 'Elenchus motuum nuperorum in Anglia,' 1662, p. 417.

Nowhere is it so severe as in Italy, especially in the Maremma of Tusca the Campagna of Rome, and the Pontine Marshes. What is of especial terest is that in these districts it has greatly increased in extent wit the last four centuries. Places which were at one time thickly popula and well cultivated have become waste and deserted; and coincidently w these changes they have grown in the highest degree unhealthy.

In Asia malarial fevers abound, not only in many parts of India, but a in Persia and in China. In Africa the west coast is but too well known the malignant character of the agues which prevail there; and ague is frequent occurrence in Algeria and in Egypt, as well as in Mozambique a Zanguebar. On the American Continent, the States which surround Gulf of Mexico are those in which the effects of malaria are most frequ and severe; they are also seen in parts of Brazil and of Peru, as well as many of the West Indian islands. It is a remarkable fact that in Austr ague is everywhere of a very mild type, if it prevails at all; and it is a to be altogether absent from New Zealand and from Tasmania.

Infection by water.—Hitherto we have assumed that malaria enters the bo with the air which is breathed; and no doubt this is usually the case. I there is good evidence that the poison is sometimes introduced in drinki water. The most striking case of all seems to be that recorded by M. Boud of the one hundred and twenty soldiers conveyed by the French transp ship "Argo" from Algiers to Marseilles in 1834. In the hurry of embar tion the water which was to be supplied to these men was taken fro marshy place near Bona. Thereupon, all but nine of them became attac with various forms of ague; and it turned out that these nine, instead drinking the same water, had purchased wholesome water from the crew the vessel, all of whom remained well. In two more ships, which made voyage at the same time, there were six hundred and eighty other soldie and they too escaped. Another instance is that of a farmer's family Houghton, near Bedford, who drank well-water, and who were at one ti almost the only persons free from ague in the parish, the other inhabita of which had only ditch-water. In another village, close by, it was noti that the digging of wells, by which a supply of fresh water was yielded, w followed by a great diminution of the disease. It seems not unlikely th to the same cause may be attributed whatever part of the decline of ag during the last few years, both in England and in Scotland, cannot accounted for by the improved drainage of the soil. Statements, however, to the prevalence of malaria in former times, cannot be universally accept since it is certain that until recently its effects were frequently confound with those of enteric fever.

Predisposition.—Of the conditions that may render one person more s ceptible to malaria than another we at present know but little. That m cases of ague are seen in men than in women or in children is doubtless d to the circumstance that men are more exposed to its exciting cause. similar explanation may be found for the fact, if it be a fact, that duri pregnancy women possess a certain degree of immunity.

It seems to be well ascertained that *negroes* are proof against ague; that black soldiers are invaluable for field service in certain parts of the We Indies. Even if this fact be due to a kind of acclimatisation, transmitt by inheritance, it is not the less remarkable. For, although ague oft attacks persons who had recently arrived in a malarious district, yet tho who have lived there for a longer time commonly suffer from malari

cachexia, being puny, sallow, and sickly. The negro, on the contrary, enjoys life and health in such regions.

It seems to be certain that over-exertion and fatigue render a man more susceptible to the action of malaria; and that those who are convalescent from other diseases, or recovering from the effects of wounds, are particularly apt to suffer. It would be worth while to investigate whether persons whose general state of circulation is such that they are prone to the disease known as paroxysmal hæmoglobinuria are more sensitive than others to the ague-poison.

Contagium vivum.—It is impossible to weigh the various conditions which favour or modify the development of malaria, without coming to the conclusion that no hypothesis accords so well with the facts as the presence of a living organism. In 1866 an American physician, Dr Salisbury, declared it to be an alga of the genus *Palmella*, which he had found in marshy soil in Ohio. But he did not attempt to show that the spores of this microscopic plant were really capable of generating the disease; and the same alga has since been discovered in regions where no ague exists. Nor were any direct proofs brought forward by other observers in Italy and elsewhere, who afterwards took up the subject, and by each of whom some different species was assumed to be the essential agent in propagating the disease. It was, therefore, a step in advance when in the spring of 1879 Prof. Klebs, of Prague, and Prof. Tommasi-Crudeli, of Rome, carried out together a series of experimental investigations which they believe have determined not only that what constitutes malaria is a particular kind of bacillus, but also that a fever of intermittent type can be generated in rabbits by subcutaneous injection of liquids containing this organism.* They constructed a machine by means of which a large quantity of air could be rapidly made to pass over the surfaces of glass slides moistened with glycerine jelly. This they set to work in the Pontine Marshes and in Rome, taking the air always from very near the surface of the ground. Direct microscopical examination of some of the glass slides afterwards revealed the presence of rod-shaped bodies and delicate threads; and by suitable methods of cultivation these were made to undergo further development into jointed filaments, with spores in their interior. Similar structures were found in mud taken from the borders of lakes in the same region. When this cultivation had been injected in rabbits the spleen, without being softened, was constantly found enlarged after death, and often contained black pigment. Finally, they cite Dr Marchiafava as having succeeded in discovering the spores and jointed filaments of the same parasite in the spleen, and in the blood of two persons who had succumbed to pernicious malarial fever in Rome.

Mr North has since with great perseverance and devotion followed the investigation of malaria at Rome, and his results differ in many particulars from those of Klebs and Crudeli ('Brit. Med. Journ.,' April 23rd, 1887, p. 865). He is inclined to regard ague as due to a primary derangement of the heat-controlling mechanism of the body, and not as the result of the invasion of microbes.

In the absence of satisfactory evidence of any pathogenic microphytes,

* I must confess that, after reading carefully the details of the experiments in question, and studying the temperature charts which Klebs and his Italian coadjutor give, I fail to see that there is anything definite or characteristic about the fever which occurred in their animals after injection of fluids containing the so-called "*Bacillus malariæ*."—C. H. F.

it was of great interest when the presence of a microscopic *animal* organ was announced as a constant occurrence in ague.

The Italian physicians, Crudeli, Marchiafava, and Celli had descri and figured remarkable pigment granules in the blood-corpuscles of mala cases.* Next, Laveran and Richard discovered pigmented amœboid bo and flagellate organisms within the blood-discs ('Comptes-rendus' for 18 Dr Osler, of Philadelphia, confirmed these observations, and in addi found, outside the blood-discs, crescentic bodies containing granules pigmented corpuscles furnished with one, two, or more flagella in ac motion. ("The Hæmatozoa of Malaria," with figs., 'Brit. Med. Jour March 12th, 1887.)

In Philadelphia, Baltimore, and Washington, American physicians the crescentic bodies so constant that they form a valuable means by wh the malarial nature of an obscure disorder may be practically ascertained

Independently of these observations in man, flagellate organisms h been described in the blood of mules in India suffering from a serious dis known in the Punjab as "Surra," by Dr Griffith Evans and Mr Steel Burma), and also by the late Dr Timothy Lewis in Indian rats ('Qu Journ. Micr. Sci.,' 1879 and 1884). Dr Crookshank has found the s organism in the blood of rats in England ('Journal Roy. Micr. Soc.,' 18 At present it is uncertain whether these apparently polymorphic bodies connected with malaria as cause or effect, or whether they are physiolog as Dr Lewis believed them to be in rats.‡

With regard to the succession of symptoms in the paroxysm of a no special explanation seems to be needed. The same order of eve more or less modified, is seen in the rigors of pyæmia. Like an epile seizure, the ague-fit has a physiological basis. Its recurrence at the s hour on successive days, or every second or third day, is doubtless, as Cu originally suggested, connected with the diurnal habit of body which i plainly manifested in other ways in both health and disease. One th fore need not wonder that Griesinger and Duchek failed to modify the ti at which ague-fits returned by changing the patient's hours of meals and other habits of life.

Diagnosis.—The recognition of ague is for the most part easy, but it m present difficulties. In places which are free from malaria, there is someti no little risk of the real nature of a patient's illness being overlooked, w he has acquired it elsewhere, perhaps while travelling in a country wh the existence of the poison was unknown to him. Again, it is an extrem difficult point to settle whether or not some of the milder and less cha teristic effects of malaria may still continue to appear from time to tim places (such, for instance, as the Borough of Southwark) in which the reg forms of ague have long been extinguished. Many experienced physici have undoubtedly held this belief.

* See Professor Crudeli's paper, with drawings of blood-discs after Marchiafava Celli, in the 'Report of the International Congress at Copenhagen,' vol. ii, p. 23.

† During a visit to the United States in 1888 the writer saw marked specimens of characteristic discs in blood taken from patients suffering from ague.

‡ The Indian species were *Mus decumanus* and *M. rufescens*; the organisms in t blood (named Herpetomonas by Saville Kent in his 'Manual of the Infusoria') have l compared to the *Spirillum Obermeieri*, to spermatozoa, to Gaule's 'Cystozoa' in fr blood, previously described by Lankester (*Drepanidium ranarum*), and to stages of Greg nidæ or other forms of Leuckart's Sporozoa.

On the other hand, in regions notoriously infested with malaria, the physician has constantly to keep in mind not only that ague is apt to complicate other diseases, but that it is capable of simulating them. Further, there is always danger of his carelessly mistaking for results of malaria other affections which are attended with recurrent rigors or with paroxysms of febrile disturbance. Thus Graves relates an instance in which the intermittent hectic of *phthisis* was set down as ague. Another disease which is very apt to be overlooked in malarial districts is *pyæmia*. In reference to this, Hertz remarks that the pyæmic rigor generally sets in more gradually than that of ague; that its subsidence is more rapid than its onset, whereas in ague the reverse is the case; and, lastly, that in pyæmia there is very seldom an interval of complete apyrexia, lasting for twenty-four or even for twelve hours. But, as we have seen, ague itself may be merely remittent. The fever attending *internal suppuration* may also be attributed to malaria. The writer once saw a case in which a medical man was firmly convinced of the correctness of such a diagnosis, until his patient voided a quantity of horribly fœtid pus with his urine, after which a rapid recovery took place. Ulcerative *endocarditis*, too, must be thought of.

Finally, there are the continuous forms of ague, with which other diseases, and especially *enteric fever*, have often been confounded. Thus in Romney Marsh no kind of fever used to be recognised except that due to the endemic malaria; and in many parts of India it is only of late years that enteric fever has been recognised. The *fièvre bilieuse hématurique* is not always easily distinguished from yellow fever in countries where both diseases prevail.

Treatment.—We have so potent an antidote to malaria in Cinchona bark, and in the Quinine which is derived from it, that some writers have classed this remedy apart from all others, as the most signal instance of a specific. It is, perhaps, the only medicine of which the efficacy is never challenged by anyone, however rash and inexperienced. The bark itself is not now prescribed, on account of its causing nausea and sickness in the large doses required; quinine or one of the other alkaloids is substituted for it. As a *preventive* of ague, quinine has been found very efficacious for sailors exposed to malaria when sent ashore for a day, for travellers passing through, or for soldiers bivouacking in, a marshy district. From two to five grains are given twice or three times a day. It is less desirable for the permanent residents in an aguish region to take quinine constantly, since its action appears to become somewhat blunted in course of time; but they may take it at the seasons when the disease is most prevalent.

There is reason to believe that the paroxysm itself cannot be modified by quinine taken after its commencement, except perhaps when it is injected subcutaneously. Probably, therefore, if one is called to a patient in an ague-fit the best plan is to prescribe a full dose of some ten or fifteen grains, as soon as possible after its cessation, repeating the same dose more or less frequently during the interval, until an hour or so before the next fit is expected. Maclean advises that the patient should never have less than thirty grains during this period. It is best given in solution with a little sulphuric, hydrochloric, or hydrobromic acid. As is well known, pills containing quinine are exceedingly apt to become hardened by time, so as to pass through the stomach undissolved. If vomiting should occur, the alkaloid may be administered per rectum in a dose of fifteen grains suspended in broth or thin starch.

When the stomach is loaded an emetic is often a useful adjuvant, and if there is constipation a purgative; but it is a mistaken practice to put off the use of quinine until the tongue has become clean.

For the actual paroxysm of ague but little treatment is needed. The patient should go to bed, and have plenty of blankets and hot bottles or hot bricks wrapped in flannel. Baths are better avoided, and he should not be encouraged to drink warm fluids in any large quantity. Frictions with stimulating liniments, or with a mixture of soap liniment and laudanum, have been recommended. It is only when threatening symptoms of collapse are present that recourse should be had to coffee, wine, ammonia or ether. As the hot stage comes on, most of the bedclothes may be removed; the patient may have cooling drinks, or he may suck a little ice, and be sponged with vinegar and water. At the end of the sweating stage he should be carefully dried and have a change of linen. He may then get up, but if he afterwards goes out of doors he must be very careful not to take cold.

It very rarely happens in recent cases of ague, when quinine is properly given, that the patient has any subsequent attack of the same severity as before; and within a few days, or in a week or two at latest, they almost always cease. But in certain cases, especially such as are of long standing and of quartan type, the remedy seems altogether to fail. The drug which then proves most successful is Arsenic. The tincture of Eucalyptus may sometimes, it is said, be prescribed with advantage. The application of cold douches to the left hypochondrium is recommended by Hertz as a valuable accessory to other treatment.

For the dangerous *remittent* and continuous forms of ague, and for those cases in which the symptoms are those of apoplexy or of some other cerebral disease, quinine is still the remedy, but it must be employed much more boldly. Maclean insists on the importance of watching for even a slight remission, using it as an opportunity of giving fifteen or twenty grains of quinine by the mouth, and repeating the dose in two hours' time. If the stomach rejects it, a similar quantity may forthwith be administered as an enema, but in the most severe cases of all he does not wait a moment, and not only prescribes quinine energetically, but also gives stimulants and plenty of nourishment. This writer also speaks in high terms of Warburg's tincture, a remedy now known to contain, in addition to quinine, aloes, rhubarb, camphor, and opium. It is a powerful sudorific.

The *malarial cachexia* requires the administration of iron as well as quinine, but even these remedies are of secondary importance in comparison with the removal of the patient to a healthy locality. Maclean speaks strongly of the value of the ointment of red iodide of mercury in the treatment of chronic enlargements of the spleen and of the liver. He directs that a piece of the size of a nutmeg should be rubbed into the skin of the hypochondriac regions, and that these parts should be then exposed to the sun or to the heat of a fire.

YELLOW FEVER*

"I say, messmate, have you ever had the yellow fever, the *vomito prieto*, black vomit, as the Spaniards call it? No? Have you ever had a bad bilious fever, then? No bad bilious fever either? Why, then you are the most unfortunate creature, for you have never known what it is to be in heaven nor else in the other place. Oh the delight, the blessedness of the languor of recovery!"—*Tom Cringle's Log.*

History—Incubation, course, and events—Morbid anatomy—Ætiology and pathology—Question of its contagious or miasmatic nature—Diagnosis—Prognosis—Preventive and curative treatment.

MALARIAL diseases are, we have seen, as common in the New World as in the Old; they are typically endemic in character. But while the true Oriental plague has never visited the Western Hemisphere, it is there replaced by an indigenous if not an endemic disease, which from time to time visits the cities of tropical and subtropical America with terrible epidemics. This specific and infectious fever is almost limited to America, the West Indian Islands, and the West Coast of Africa. Although it has sometimes been imported into Europe, it has never maintained itself among us. In the East it is altogether unknown.

The first epidemic on record was in 1647, when it appeared in Barbadoes, and was called *nova pestis*. A destructive pestilence of the same kind appeared at Philadelphia in 1693, and again in 1762, 1793, and 1802. It visited Mauritius in 1815, and Gibraltar in 1804, 1814, and 1828. It is endemic in the island of Hispaniola (Haiti and San Domingo), and more or less frequent throughout the West Indies and the adjacent coasts of Mexico, Guiana, and the southern United States. It first appeared on the Brazilian seaboard in 1849, at Buenos Ayres in 1858, and at the port of Callao in 1853. Between 1780 and 1820 it repeatedly occurred in Cadiz and other Spanish ports, in 1821 at Barcelona, and afterwards at Marseilles and Leghorn. There was a terrible epidemic at New Orleans in 1878, and in Florida in 1888. Its range is certainly wider than it was in the last century. There was an epidemic in Lisbon in 1857, and another at Swansea in 1865, introduced from Cuba in the barque "Hecla;" but happily this did not spread.

Course.—The incubation of yellow fever is short, rarely above a week, but it may be considerably longer.

There are sometimes slight prodromal symptoms of malaise and headache; but the disorder often sets in suddenly with rigors and extreme depression. Sometimes it proves fatal in a few hours with collapse and lividity. More often the temperature rises for two or three days until it reaches 105° Fahr., or, as was once recorded, 107°; the face becomes flushed, the conjunctivæ are red and ferrety, and the eyes bright and staring. Frequently there is one-sided headache, or an agonising pain in

* *Synonyms.*—Typhus icterodes—Bilious Typhoid Fever—Black vomit—Yellow Jack—Specific diffuse Hepatitis—Icterus gravis with parenchymatous hepatitis—Calentura vomito-negro—Coup de barre—Mal de Siam is probably a bilious remittent, not Yellow Fever.

the back and sacrum, or there may be pains in all the joints. The stomach becomes very irritable, and rejects its contents; the epigastrium is tender to pressure. The palate is reddened and œdematous; the gums may be swollen and inclined to bleed; the tongue is furred at first, but afterwards clean, smooth, and raw-looking. Constipation is more frequent than diarrhœa. The urine is very scanty, with deficient urea, and it generally contains albumen.

About the third day, or a little later, the next stage succeeds—the "lull," or *stadium* of the fever. The skin becomes jaundiced; the urine is bile-stained; but the fæces are seldom clay-coloured. Hæmorrhage now occurs from various surfaces; epistaxis is frequent, and sometimes there is cutaneous purpura; the vomited matters, from being "white" and consisting of an acid watery liquid, become "black," containing dark brown flocculi or larger masses made up of altered blood-corpuscles. It is to be observed, however, that this symptom of *black vomit* occurs only in the more severe forms, and chiefly in such as end fatally. Thus, during an epidemic at Gibraltar in 1828, Louis found that of the patients who died, all but one had it, and of those who recovered very few. According to Alvarenga, however, at Lisbon, in 1857, there were no fewer than forty recoveries among cases in which black vomit was present.

Haenisch, the writer on this subject in 'Ziemssen's Cyclopædia,' who has himself seen the disease in the West Indies, states that there is usually on the fourth day a remission of the pyrexia, so that the temperature in twelve hours may fall nearly to normal. At the same time the patient loses his headache, and experiences so much relief that he fancies himself out of all danger. The stomach, however, still remains irritable; and the urine, if not previously albuminous, now becomes so. In some cases the improvement is permanent, and goes on to complete convalescence. But more often, after a few hours or within two days at the longest, matters change again for the worse. The temperature may now rise until it reaches 104°; but sometimes remains normal, as, for instance, in a patient of Mr Leggatt who died of yellow fever in London in 1878 ('Clin. Trans.,' vol. xi).

The symptoms at this period seem mainly to depend upon disturbance of the renal secretion. The urine is often entirely suppressed for several days together; it always contains albumen, and frequently blood-casts. The patient sometimes falls into an apathetic condition, but is more often restless and talkative, and sometimes he becomes violently delirious. The pulse is small and thread-like, sometimes rapid, sometimes slow. The jaundice increases until the skin acquires a dark mahogany colour. Hæmorrhage continues, blood being passed from the whole length of the intestine, from the female genitalia, from the external ear, or from the respiratory surface. Death is usually preceded by coma, but sometimes it occurs suddenly, the patient falling backwards upon his bed in syncope, after a state of violent excitement. But recovery may take place even when the case has appeared most threatening—usually by crisis, with a rapid fall of temperature and profuse sweating.

Among the *sequelæ* observed are suppurative parotitis, sloughing of the scrotum and penis, and the formation of boils containing blood mixed with pus. Convalescence is always slow, and several weeks elapse before the patient regains his strength.

During an epidemic of yellow fever cases occur, in which the symptoms are but slightly pronounced. The pyrexia is moderate in degree; there is

but slight jaundice, or it may be altogether absent, or may appear only when the attack is passing off. In this respect yellow fever resembles typhus, scarlatina, and plague.

The *protection* afforded by this disease against second attacks is said to be very efficient. Even relapses are rare.

Morbid anatomy.—Rigor mortis is early and well marked; and, according to Nielly, putrefaction is retarded, which is not what one would have anticipated. The body is deeply jaundiced, more deeply sometimes, says Dr Macdonald, than it was during life. The heart is often pale and soft, and the fibres in a state of fatty degeneration. The pleuræ are ecchymosed, the lungs purpuric, and hæmorrhage is found between the muscles and under the serous membranes or the meninges of the brain. There is usually acute catarrh of the whole length of the alimentary canal, and the stomach sometimes shows hæmorrhagic erosions; but in Mr Leggatt's case the stomach was pale, and its mucous membrane was not swollen. According to Macdonald, the stomach appears perfectly normal when the digested black blood is washed off.

The *liver* may present patches of a bright yellow colour, or its tint may be that of coffee; and all observers agree that in Mr Leggatt's case, Dr Greenfield, who made the autopsy, found that the portal canals were crowded with leucocytes, that many of the bile-ducts were filled with swollen epithelium, and that the greater part of the hepatic cells were undergoing disintegration, being swollen and fused together, or broken up into irregular fragments. It may, however, be a question whether in this case the state of the portal canals was not an accidental cirrhotic change, due to the known habits of the patient. If not, Dr Greenfield's observations tend to support a doctrine, upheld by Liebermeister in his work on 'Hepatic Diseases,' that yellow fever is nothing else than a "parenchymatous hepatitis" dependent upon a specific infection. This view is supported by Dr Wickham Legg in his work on the 'Bile and Jaundice,' where he cites the description of microscopical appearances by Dr Alonzo Clark, of New York, and several other observers. Acute fatty degeneration with atrophy is constant, and all observers agree that the hepatic cells are loaded with fat globules. The biliary passages are found free from obstruction, and the gall-bladder contains sometimes tarry bile, sometimes colourless, thin mucus.

The spleen is but slightly if at all enlarged; its tissue is often firm and healthy-looking, and it is not infrequently shrunken—probably as the result of gastric hæmorrhage.

The kidneys are enlarged and may show points of suppuration; in the case already referred to, Dr Greenfield found the epithelium of the convoluted tubes swollen and proliferating, and the straight tubes contained hyaline casts; but the kidneys were in this instance granular, so that these changes may have been unconnected with the yellow fever. According to Dr Legg, however, a condition of cloudy swelling like that found in the early stage of parenchymatous nephritis is the rule.

Ætiology.—With regard to the origin of yellow fever there have been great differences of opinion. One of the most striking features of the disease is that its infectious principle is often transported by ships. Of this a few instances have become historical. In 1823 H.M.S. "Bann"

carried yellow fever from Sierra Leone to the island of Ascension. In 1845 the "Eclair" steamer brought it from the African coast to Boà Vista, one of the Cape de Verde Islands. In 1861 it was conveyed by a wooden sailing ship, the "Anne Marie," from Havannah to St Nazaire, in France; and in 1865 by a similar vessel, the "Hecla," from Cuba to Swansea. Moreover, the disease frequently passes from one ship to another, not only where they have been lying side by side in the same port, but also on the high seas. The "Anne Marie," for instance, infected seven other vessels which happened to be brought near her; and during the local epidemic at Swansea a smack, the "Elinor," which took in cargo near the "Hecla," had her crew attacked after they had left that port and had reached Llanelly. So, in 1795, the "Hussar" frigate captured a French ship, the "Raison," on which yellow fever was prevailing; only those prisoners who were believed to be in perfect health were transferred to the English vessel, but notwithstanding this precaution the disease soon broke out on board the prize.

These facts are best explained by supposing that yellow fever, like typhus and the exanthemata, is propagated by a contagious emanation from the bodies of the sick; the infection, like that of plague, has often been found to cling to the hull, or perhaps to the cargo, of a particular vessel, after the crew have been paid off. It is believed in the West Indies that a cargo of hides or of sugar is favourable, and one of salt unfavourable, to the development of yellow fever on board, or to its transfer from one port to another, even when the crew escape.

In the 'Med.-Chir. Review' for 1848 and subsequent years there appeared a series of able articles, which are now known to have been written by the late Dr Parkes, in which evidence was offered that yellow fever is contagious. He relates in full detail the circumstances which attended its diffusion in Boà Vista from two soldiers, belonging to the fort, who were lodged while ill in the chief town of the island, Porto dal Rey, as well as from a labourer, who brought it direct from the "Eclair" into another town, Robil; and in each case he shows that the next persons to be attacked were those who lived close to the patients and visited them.

On the other hand, many of those who have had the largest acquaintance with yellow fever have disbelieved in its contagiousness, in the ordinary sense of that term, and many facts have been adduced in support of their view. One is that, as Griesinger has pointed out, the disease often remains localised upon the sea-shore, or in close proximity to the banks of a navigable river; it may even confine itself to a small part of a seaport town in the immediate neighbourhood of the harbour. Thus, when it prevailed at Lisbon in 1857, one hundred and eighty-two persons are said to have left the city for different places in Portugal, carrying with them the disease, and eighty-six died, but in no instance was it communicated to other persons in the places whither they went. In 1865 Dr Buchanan, having investigated with great care the local epidemic at Swansea, came to the conclusion that "the evidence tending to negative personal contagion was about as strong as such evidence can by its nature ever be."

Climate.—Yellow fever only flourishes in hot climates—a further reason, perhaps, for supposing that its infective principle multiplies outside the human body and subject to atmospheric influences. The regions in which the disease commonly prevails are all situated near the equator; and the occurrence of a local epidemic within the temperate zone seems constantly to be associated with an exceptionally sultry state of the weather at the time.

This was the case at St Nazaire, in France, when it developed itself there in 1861; and also at Swansea, in 1865. The latitude of Swansea is 51° 37′, which is beyond the geographical limit usually laid down for the disease. So, again, upon low coasts and near the mouths of rivers, the worst months are generally July, August, and September; although in small rocky islands within the tropics the period from October to February is stated to be the most dangerous. Some exceptions, however, to the rule that the contagion of yellow fever cannot resist cold have been recorded. Thus Dr Archibald Smith recorded, in the first volume of the 'Transactions of the Epidemiological Society,' the fact that in 1855 it prevailed at Cuzco, in the Peruvian Andes, where (as he was informed) the temperature of summer rarely, if ever, reaches 65° Fahr. in the shade; and also at Cerro Pasco, with a mean temperature of 44° by day. So, again, Mr Leggatt's patient, who died in London, was taken ill on March 21st, 1878, the mean temperature of the four previous days having been 54°. He had arrived at Southampton from Rio Janeiro (where the disease was epidemic) on March 17th, and there had been three cases of yellow fever on board the ship.

Many physicians believe that the disease is not contagious from the sick to the healthy, but that its germs are carried on the clothes of healthy persons, who thus spread the infection in the same way as other "fomites," merchandise, or, above all, ships. It is quite in accordance with the analogy of enteric fever, of plague, and of cholera, that though infective, and derived only from a previous case of the disease, yellow fever should not usually be propagated by direct contact, but by less obvious transference of a virus.

It is remarkable that yellow fever does not occur among negroes, and less, it is said, among mulattoes or quadroons than in those of pure European blood. According to Humboldt, the Indians of South America are also exempt.

Men are more often attacked than women, and adults than children and old people—facts which probably depend on the usual spread of the disease in epidemics being by commercial intercourse.

Pathology.—Yellow fever is certainly a specific disease in its origin as in its course, and the above ætiological facts point to its being miasmatic-contagious (cf. p. 12), although of this there is at present no proof. Dr Parkes, indeed, in the articles above referred to, maintained that yellow fever is, or may be, developed out of ague, which, he supposed, undergoes conversion from a non-contagious into a contagious disease. He considered it to have been proved, for example, by Dr Bryson that when the "Eclair" left Sierra Leone on her way to Boà Vista, there was no yellow fever in the former place, so that the crew of that vessel must be supposed to have derived the fever from "endemic sources" in the soil water or vegetation, to which they were exposed both in their boat-services and in unhealthy anchorages.

It is now, however, universally admitted that yellow fever is quite distinct from any form of intermittent or bilious remittent fever of malarial origin; for its geographical range is quite different, it is epidemic, it is transmitted from place to place, it consists of a single attack and protects against future invasion, albuminuria is constant, the spleen is not enlarged, and quinine, so far from being a specific remedy, is believed to be injurious; and no pathologist would now maintain that a malady so distinct in its origin, symptoms, anatomy, and natural history, can be developed out of an admittedly different

group of disorders. Moreover, it is obvious that the facts cited by Dr Parkes with regard to the spread of the disease at Boà Vista are quite consistent with the hypothesis that the infective principle of the disease—having once been introduced into the island from the "Eclair" upon clothing or upon the persons of those who landed from the ship, or having even been carried into Porto dal Rey by the soldiers who were taken ill in the fort—afterwards established itself in the soil, and flourished as a miasm. Moreover, it seems probable that when infection clings to the hold of a ship, the requisite nidus for a specific microphyte may be afforded by the bilge-water.

No microbe has yet been discovered, though it was carefully searched for with all the modern methods of detection during the epidemic in Florida and Cuba in the year 1888.

A question remains as to the relation of yellow fever to other forms of malignant jaundice (*icterus gravis*). Grisolle, Garnier, Liebermeister, and Wickham Legg, maintain that the two are identical, and that the cases of acute yellow atrophy of the liver which occur in Europe are sporadic cases of yellow fever.

This can scarcely be. The absence of fever in the former, and its presence and height in the latter; the atrophy as well as softening and degeneration of the liver, the swollen spleen, and the entirely non-contagious character of the former; to say nothing of the absence of hæmorrhagic vomiting and the presence of leucin and tyrosin in the urine—all these facts prevent our identifying the two diseases. But the icterus, the hæmorrhages, the rapid course, and the histological change in the liver, with the affection of the kidneys, show a close relation between them.

Diagnosis.—This is not always easy except when yellow fever is known to be prevalent. The affection most apt to be mistaken for it is the bilious form of remittent fever. Other diseases that must be borne in mind are relapsing fever and the various local forms of jaundice attended with pyrexia, acute yellow atrophy, and also poisoning by phosphorus. The distinction from remittent malarial fever has already been indicated.

The "bilious typhoid" described by Griesinger in Egypt and the Siamese fever of French writers were both probably bilious remittent fevers, and not, as has been supposed, yellow fever.

Prognosis.—Yellow fever is a dangerous pestilence—very different in this as in other particulars from malarial fevers. The mortality seems to vary widely in different epidemics, being sometimes as low as 15 per cent., sometimes as high as 75 per cent.

Even in the comparatively mild visitation of New Orleans in 1878 more than 4000 people died, and there were about 4000 deaths at Barcelona in the year 1821.

The general indications are that the greatest danger is in the case of drunkards, and of those who go about while the fever is already upon them. In children the prognosis is favourable.

In a given case, the severity of the initial pyrexia is not of bad omen; but much hæmorrhage, and particularly hæmatemesis, in the second stage, and the presence of petechiæ, severe cerebral symptoms, convulsions, and stupor, with dilated pupils and suppression of urine, are very unfavourable and often fatal symptoms.

The symptom of most value as regards prognosis at an advanced stage

is said to be albuminuria; if the amount of albumen in the urine diminishes as the case goes on, the patient is likely to do well; if it increases, a fatal termination is to be apprehended. Ordinary bilious vomit is accounted a good sign, hæmatemesis and black vomit a bad one.

Quarantine.—If yellow fever is a contagious-miasmatic disease, the precautions which should be adopted in order to prevent its transport from one country to another may be greatly simplified, in comparison with the regulations laid down until recently by the best authorities, as, for instance, by M. Mélier in France after the St Nazaire epidemic in 1861. As Sir John Simon remarks in his 'Eighth Report,' the segregation of persons arriving from an infected town, and their confinement in a lazaretto for a definite period of time, is, on this view, superfluous, and in a trading country like England, all but impracticable.* The points to which the whole energies of a port sanitary officer should be directed are the isolation and disinfection of the vessel which is known or suspected to contain the virus of the disease. It should be compelled to anchor at a distance from all other vessels; and every part of the hold should be thoroughly cleansed. It would now be advisable to use carbolic acid for this purpose, rather than the chloride of lime, which M. Mélier recommended. The cargo, and the clothes and other effects of the sailors and passengers, should be disinfected at the same time.

The necessity for stringent precautionary measures against the development of yellow fever in England and in other temperate climates is very much diminished by the fact that a high external temperature is believed to be a very important, if not essential, factor in its ætiology.

Treatment.—The treatment of yellow fever is mainly symptomatic. Quinine is useless or injurious. At the beginning, some experienced physicians give a purge of calomel, jalap, and ginger. The cold pack has proved useful in many cases, but mustard applied to the legs, or a hot footbath, appear to be preferable at the onset. For the relief of sacral pains dry cupping may be used. The irritability of the stomach may be checked by the administration of creasote or a few drops of hydrocyanic acid, chloroform, or chlorodyne. The patient should be fed with bland nutriment, such as thin arrowroot, barley-water, or chicken broth. Ice is used, if it can be obtained; and it seems to be the usual practice to allow the patient champagne or brandy, well diluted with water, during the second stage. In one case recorded by Dr Macdonald, the cook of H.M.S. "Icarus" very nearly succumbed in the second stage, "but he rallied immediately on the administration of a stout glass of rum and water and recovered steadily." Notwithstanding the almost constant presence of albuminuria and the not infrequent supervention of uræmic symptoms, physicians experienced in the treatment of this disorder use subcutaneous injections of morphia to relieve vomiting.

* Quarantine (Fr. *quarantaine*, a period of forty days) was introduced by the Republic of Venice in 1348, to prevent the invasion of the Oriental Plague, or Black Death as it was then called. In England it was enforced by law under Queen Anne (1710) in order to prevent the return of plague, and a fresh Act was passed in 1727 by the advice of Mead, after the terrible pestilence of measles in the preceding year. No plague appeared, but the quarantine laws became absolute until the beginning of the present century, when their uselessness was seen. Since 1831, the same precautions have been in force in many parts of Europe against Cholera. In the New World, and also in Spain, quarantine regulations have also been adopted to prevent the invasion of Yellow Fever.

HORACE.

History—Course and symptoms—The fever and the interval—The exanthem—Sequelæ—Pathology—Contagion—Diagnosis—Prognosis—Treatment.

AMONG the new epidemic fevers of the present century is one which, like yellow fever, is unknown in England: but it is common in India and some of the colonies. It clearly belongs to the group of specific diseases, and is perhaps most like influenza.

In 1824 this disease, hitherto unknown to Indian surgeons, broke out at Rangoon in Burma, and quickly spread to Calcutta and to various places in Bengal or in Madras. In 1827 the same malady appeared in the West Indies in the Isle of St Thomas, and a few weeks later in the adjacent Isle of Santa Cruz. Here also it was at first regarded as a new disease; but it has since been found that Dr Rush, of Philadelphia, described it as prevailing in that city in 1780. During the last fifty years it has from time to time attracted attention both in the Eastern and the Western tropics. There was an outbreak in India in 1871–72, when it is said to have been derived from Zanzibar, passing to Bombay by way of Aden; in 1873 it spread to China and to Cochin China, and also to the islands of Mauritius and Réunion. In the West Indies it was last seen at Martinique in 1874 and in 1875. The only spot in Europe in which this malady has hitherto appeared is Cadiz, where it was observed by Poggio in 1867; and an earlier epidemic is said to have occurred in the same town as far back as 1784. Recent accounts tell of the same disorder as an epidemic in the Levant (1889).

In St Thomas the negroes called the new disorder "dandy fever," apparently in ridicule of the attitude and gait of the patient; and it is now universally known as Dengue—a Spanish word, of similar meaning.

Course.—Dengue sometimes sets in with lassitude, drowsiness, vertigo, a sensation of chilliness down the back, and other febrile symptoms; but more often it begins suddenly with pain in some particular part of the body, coming on while the patient is walking about, or in the night, waking him from sleep. Dr Stedman, who, in the 'Edinburgh Med. Journ.' for 1828, gave an excellent account of the disease in St Thomas, says that the first thing noticed was often a stiffness in one finger, especially the little finger; this would increase and be accompanied by intense pain, which spread over the whole hand and up to the shoulder; and in a few hours the fingers of both hands would be swollen, stiff, and painful, and their joints incapable of being bent. It does not

* *Synonyms.*—Dandy Fever—Breakbone Fever—Three-day Fever—Scarlatina Rheumatica—Febris exanthematica articulosa. Other absurd names are "broken-wing fever," and "giraffe," the latter because the neck is held in a stiff position. The word *Dengue* has been coined as a Latin name of the disease, but *Dengue* is the form used by French and German as well as English writers.

appear that effusion can be detected in the joints, as in rheumatic fever; but Hirsch says that, in the rare cases of death, serous infiltration has been found in the connective tissue round certain joints. Cotholendy, in describing dengue in the Isle of Réunion, suggests that there is an exudation into the sheaths of the tendons, and especially of the extensor tendons, and that it is this which renders movements of the joints so exquisitely painful; and he also speaks of "a slight fulness, a sort of œdema," of the hands and feet. There is often violent pain in the eyeballs, which feel too large for their sockets and as though they would start from the head. Before long every part of the body becomes the seat of extreme suffering, aggravated by restlessness, which compels the patient to be constantly changing his position. He also feels extremely prostrate and distressed. Sleeplessness is a marked symptom, and children are sometimes delirious.

In the meantime the temperature rises until it reaches 102°, 103°, 104°, or even (though very rarely) a higher point still. Observers who have employed the thermometer during some of the more recent epidemics have attached some importance to remissions, which occur three or four times in the twenty-four hours. Most writers have described the pulse as very rapid, 120 or even 140 in the minute, but a writer in the 'Arch. de Méd. Navale' for 1874, says that he often found it not much over 80, far lower than might have been expected from the temperature. Twining long ago noticed that the countenance was flushed and of a scarlet hue, and recent observers describe an exceedingly fugacious *initial rash*, consisting of bright red patches upon the face, the chest, the palms of the hands, and elsewhere, which, however, subsides after the lapse of a few hours. There is anorexia; the tongue is thickly furred, with bright red edges. The stomach is extremely irritable, and often rejects everything that is swallowed. The bowels are constipated.

The condition of the patient at this period might well cause considerable anxiety to anyone unacquainted with the disease; but at the end of twenty-four or thirty-six hours the pyrexia begins definitely to subside, without any marked critical sweat, and the temperature soon falls to normal or slightly below it. At the same time the pains in the limbs cease, and soon there is nothing for the patient to complain of except a sense of general weakness, loss of appetite, and backache. At this time it is said that the glands in the neck, the axillæ, and the groins may be felt to be slightly enlarged. The parotid is often swollen and salivation is frequent.

The duration of the interval is about three days. At the end of this time an exanthem—the *second rash*, according to recent observers of the disease—appears upon the skin. It is first seen upon the palms of the hands, next on the feet and the knees, and may in exceptional cases spread all over the body. In appearance it is usually intermediate between the rash of scarlet fever and that of measles, and it has also been compared with the erythema that sometimes accompanies rheumatic fever. In some cases it is attended with the formation of bullæ or of wheals like those of urticaria. It gives rise to a distressing sensation of tingling, which presently passes into still more intolerable itching. Its development is sometimes associated with a return of pyrexia, but recent observations seem to have shown that, as a rule, the temperature remains normal at this period of the disease. Consequently the fact that an eruption has made its appearance is not seldom overlooked; whether it is ever really absent is doubtful. After a few hours, or two or three days, it subsides and disappears, and with it the

fever, if any. Afterwards the cuticle begins to desquamate, usually as a branny powder, but sometimes in large flakes, and this may be attended with considerable discomfort and soreness, especially of the feet.

The second eruption is often associated with a repetition of the articular pains, which are, however, less severe than at the beginning of the disease. Or there may be a respite of three or four weeks, and at the end of that time the pains may return, compelling the patient to take to his bed again and be fed like a child. Dr Stedman speaks of these pains as always most severe in the morning and as wearing off in some measure towards evening. They are felt chiefly in the fingers and toes, in the wrists, the ankles, and the knees. The affected joints may be so stiff and swollen as to produce deformity. After a few days the secondary pains in their turn begin to subside, and one limb after another becomes free.

Bronchitis may occur as a complication, and Nielly has occasionally seen pericarditis in severe cases. Months may elapse before the patient is entirely exempt from return of pain, and the weakness is long-continued and distressing.

Pathology and causation.—The true place of dengue among infective diseases has yet to be accurately determined. In the rapidity with which it spreads over a population it resembles influenza more than any other malady.

A remarkable point is that scarcely anyone escapes, even among the inhabitants of a large city, as, for example, among the half million of residents in Calcutta in 1824. It attacks persons of all ages, including even infants a few days old, and the coloured races are as liable to it as whites. When it has lasted for a little time, one might think that there were none but cripples in the place, so many are seen limping about the streets on crutches, with bodies half-bent or with arms in slings. The duration of an epidemic is from two to seven months, according to Hirsch.

The disease is said to prevail chiefly with sultry, cloudy weather or at the time of heavy rains. In temperate climates it occurs only during summer and autumn, and disappears when frosts set in; but in the West Indies vicissitudes of weather seem to have no way interfered with its course. Its diffusion from one country seems plainly to be effected by human intercourse. Whether it is contagious in a restricted sense, passing from the sick directly to the healthy, is uncertain. Dr Stedman says that in 1827 it was introduced from St Thomas into Frederickstadt, a town of Santa Cruz, by some young ladies who went to stay at a house where all the members of his family were attacked, and a few days later it appeared in the next house and affected everyone there. Cotholendy relates that an infant, which had taken the disease while with the family of its nurse, was brought home to its mother; four days afterwards she fell ill; the grandmother and the aunt did not see the child until the day after its arrival, and they were attacked a day later than the mother.

He gives several other instances which indicate that the *incubation* of dengue lasts four days.

No distinctive morbid anatomy is known, and nothing has yet been ascertained as to the nature of the infective virus.

Diagnosis.—The epidemic character and the peculiar rash, with the immunity of the heart, distinguish this singular disease from rheumatism,

the articular pains and absence of sore-throat from scarlatina or measles. It is not malarial, for it affects the whole population equally; there is no splenic enlargement, and quinine is useless.

Prognosis.—Dengue is scarcely ever fatal, but infants sometimes die with convulsions during the primary pyrexia, and old people may succumb to exhaustion towards the end of the disease, or to bronchitis. When untreated, recovery is said to be very slow.

Treatment.—It is recommended to give an emetic at the onset of the malady, and then a purge of calomel and scammony or jalap, repeated each day. After the bowels have been freely opened, a dose of laudanum, or Dover's powder, completes the cure. Liniments of chloroform, belladonna, or cajeput oil are often useful, and Dr Stedman found that the application of mustard plasters or blisters to the neck or to the loins gave great relief. When the joints remain stiff and painful after the subsidence of the disease, sulphur baths are said to be very efficacious.*

* For valuable observations on the clinical characters and the treatment of dengue, as well as of yellow fever, the reader is referred to Dr Shattuck's notes to the American translation of Strumpell's 'Handbook of Medicine.'

EPIZOOTIC DISEASES

OCCASIONALLY TRANSFERRED TO MAN

"Nec tondere quidem morbo illuvieque peresa
Vellera, nec telas possunt attingere putres.
Verum etiam invisos si quis tentarat amictus,
Ardentes papulæ atque immundus olentia sudor
Membra sequebatur; nec longo deinde moranti
Tempore contactos artus sacer ignis edebat."

VIRGIL (of Cattle Plague).

Οἱ δὲ ὄνοι μάλιστα νοσοῦσι νόσον μίαν ἣν καλοῦσι μηλίδα· γίνεται δὲ περὶ τὴν κεφαλὴν πρῶτον, καὶ ῥεῖ φλέγμα κατὰ τοὺς μυκτῆρας παχὺ καὶ πυῤῥόν.—Aristotle, 'Hist. Animal.,' lib. viii, cap. 25 (of Glanders).

THERE are certain epizootic maladies which sometimes pass from animals to man. These may conveniently be classed together in this last chapter on the specific contagious and epidemic maladies.

ANTHRAX.*—This name, formerly used as a synonym for carbuncle, is now applied to a very different disease which human beings derive by infection from sheep, horses, and oxen.

With regard to the *geographical distribution* of anthrax as a disease of cattle, the parts of Europe in which it is most common are Poland, Hungary, the countries of the Lower Danube, Prussian Saxony, and certain departments of France. It is endemic in Catalonia, in the Romagna, and in Courland, and often prevails in Siberia and in Lapland, in Western Asia, Australia, Mexico and South America, in India, and in South Africa. It is not endemic in this country.

Anthrax occurs not only in domesticated animals, but also in deer,

* *Synonyms.*—Splenic Fever—Splenic Apoplexy—Malignant Pustule.—Siberian Cattle-plague ("Jaswa"). In India it is known as "the Loodiana plague," and at the Cape as "Horse sickness." *Old English* Blackbain, *Fr.* Charbon, Mal de Chabert, *Germ.* Milzbrand.

reindeer, buffaloes, and elephants. It also affects swine, and is easily inoculable upon rabbits and guinea-pigs. Carnivorous animals are much less susceptible; but cats are more so than dogs.

Varieties in cattle.—In different kinds of animals the symptoms of infection by the specific virus of anthrax differ considerably. But, according to Bollinger, three principal varieties may be recognised:

1. Sometimes the animal (generally an ox or a sheep) becomes convulsed and insensible, with rapid breathing, and dies after a few hours.

2. Other cases are characterised by pyrexia, which is often remarkably remittent in type. Clonic spasms of the limbs are also observed. The fæces may contain a large quantity of blood.

3. In yet other cases the most marked feature is the formation of brawny inflammatory swellings in and beneath the skin of the neck, chest, abdomen, or any other part, which may lead to extensive sloughing and ulceration.

Obviously only the last of these varieties would naturally be termed anthrax. But it is on every ground desirable that a single name should be given to them all. Indeed, although veterinary pathologists until lately regarded the more rapidly fatal cases as examples of a specific fever without localisation, it is now known that there always is a local lesion in some part of the body. Very often this consists of an infiltration of gelatinous exudation and blood into the connective tissue of the abdomen and of the chest. Or there may be an acute inflammatory swelling of the tongue, or of the submucous tissue of the pharynx, or of the lining membrane of some part of the intestine. We shall presently see that all these forms of the disease are also met with in men. Anthrax is by no means always fatal to animals; the average mortality in horned cattle and in horses is said to be 70 per cent. The characteristic lesion, found after death, is enlargement of the spleen, which is from two to five times its normal size, softened, and of a black colour.

The Bacillus.—The proof of the identity of the various forms of anthrax lies in the fact that all are caused by a single microphyte, which is now commonly known as the *Bacillus anthracis.*

This organism was discovered independently by two German observers—by Pollender in 1849, by Bräuell of Dorpat in 1857. But Davaine was the first who, in 1863, maintained that the contagion of the disease lay in these bodies, which on account of their being motionless he distinguished from the common mobile bacteria of putrefaction by the name of *bacteridia.* They consist of straight or slightly-bent rods, measuring 0·007—0·002 mm. in length. Dr Frisch and Dr Cossar Ewart have under certain circumstances observed movements in them, but as a rule they are motionless. By Cohn they have been classified as a bacillus which he termed *Bacillus anthracis,* though he observes that it is almost exactly like the *Bacillus subtilis* which constitutes the butyric acid ferment, except that the latter is motile.

The rods sometimes cohere together at their extremities, and Koch and Ewart have described them, when cultivated in aqueous humour as growing into long filaments, in the interior of which bright granules appear—the spores of the bacillus, far more capable of resisting heat and desiccation than the adult microphyte, and retaining for an indefinite length of time the power of development into the mature form. Nägeli maintained that the bacilli of anthrax, like putrefactive bacteria, multiply only by fission; and there is no doubt that *Bacillus anthracis* does multiply by fission under the

surface of an infusion, but by spores when exposed to air, and also, under certain conditions, by assuming a Torula form. These facts have been ascertained by Klein and other independent observers, so that Koch's original statement is abundantly confirmed. The bacilli are found in the blood, spleen, and many other organs (see Dr Crookshank's 'Bacteriology,' pl. xiv, fig. 1; xvi and xvii, fig. 1).

Infection.—The origin of anthrax, as it occurs in cattle, in horses, and sheep, is of great interest, and throws light upon the class of diseases known as *miasmatic-contagious* (p. 12), to which it belongs.

In the first place, it is readily transmissible by means of the blood from a diseased to a healthy animal. Inoculations are frequently and successfully practised by veterinary surgeons and by pathologists for diagnostic purposes.

There is reason to believe that the virus is not infrequently introduced by the stings of insects: Bollinger took gadflies from the body of an ox that had died of anthrax, and found by direct experiment that the contents of the stomach and intestines of these flies were capable of conveying the disease to rabbits. Another way in which it is sometimes given to sheep is by the bite of a dog that has just been feeding upon infected flesh.

There is not sufficient proof that secretions from the bodies of living animals affected with anthrax pass into the air and infect other animals through the lungs. Like enteric fever, yellow fever and cholera in man, this disorder is not directly contagious; yet the virus sometimes clings to stable utensils, harness, straw, or hay. Bollinger mentions a local outbreak which he carefully investigated at Weriken, and in which for four years the cattle in two sheds of the same proprietor were decimated by anthrax, while it did not affect those in other buildings, closely adjacent. An analogy for this occurrence may be found in those local house-epidemics of enteric fever in which the virus seems to go on multiplying itself in or near a particular water-closet, so as to affect a number of persons in succession, sometimes at long intervals of time.

Anthrax also resembles the miasmatic-contagious diseases of man in being often spread in ways still more indirect. It prevails among animals pastured upon damp soils containing much humus, as, for instance, upon peat-bogs, and near the borders of lakes or rivers that have overflowed. And it is most frequent during the hot months of the year, particularly in August and September.

Buhl has included anthrax among the diseases to which he applies his "ground-water" theory (cf. pp. 240–1), and he states that among the horses belonging to a large stud kept near Donauwörth the disease, which had been raging for a long time, ceased as soon as a system of drainage was carried out. But Bollinger argues that the reason why its prevalence is affected by dampness of soil is, in reality, that ground containing moisture affords conditions favourable for the multiplication of the *Bacillus anthracis*, which he supposes to be capable of maintaining an independent existence under such circumstances.*

* Some observers have thought that this organism may sometimes appear without having been derived from a previous case of anthrax. Buchner asserted that, by a series of experiments, he converted a bacillus which is found in infusion of hay into an organism capable of producing in animals an infective disease identical with anthrax, and he asserts that to turn the anthrax-bacillus back into a hay-bacillus is comparatively easy. There is, however, good reason to disbelieve this alleged transformation. See Professor Klein's Report to the Local Government Board, "On the Relation of Pathogenic to Septic Bacteria, as illustrated by Anthrax Cultivations" (Blue-book for 1882).

Anthrax is never purely *miasmatic*. Its specific bacilli exist in the soil, or in water, only when they have been introduced from a previous case. They may be either derived from the excreta of diseased animals, or from their dead bodies, buried as they often are in the fields, or left to rot among the brambles and nettles. Instances are recorded in which "enzootic" anthrax has ceased so soon as stringent rules for the disposal of all dead bodies were enforced. Probably some of the bacilli from the infected carcases become free, undergo desiccation, are suspended in the air, and inhaled into the lungs; others pass into drinking-water, and thus reach the stomach, while others, again, may gain access to the lymph-spaces and blood by some breach of surface in the skin.

Conveyance to man.—Shepherds, farm-labourers, and other persons who come into contact with living animals affected with anthrax seem seldom or never to take the disease by mere *contagion*. But veterinary surgeons may be infected in performing venæsection, and slaughterers in killing or in skinning; the probability is that a slight abrasion or scratch upon the skin then becomes directly inoculated with the virus.

Another way in which anthrax may arise in man is as the result of *eating the flesh* of an infected animal. Leube, of Jena, has recorded an instance in which the imperfectly cooked liver of a diseased goat conveyed it. Thus the human gastric juice seems not necessarily to destroy the virus, as has been found to be the case with the gastric juice of carnivorous animals such as the dog. Thorough cooking probably removes all danger, but there still remains the risk of injury to the butcher, and to those who are concerned in preparing such meat for the table; and this is sufficient reason why the use of it, as food, should be prohibited. According to Heusinger the disease may even be conveyed by milk or by butter.

But by far the most important cause of anthrax in man is infection *from the dried skins or hair* of diseased animals. In this way it is brought straight from Asia or South America to English workmen.

At Guy's Hospital cases are of not infrequent occurrence among the men engaged in the Bermondsey leather trade, and especially among those employed at a particular wharf on the river-side where foreign hides are unshipped. Broca years ago remarked how often anthrax was set up by carrying skins upon the shoulders. It is remarkable that the danger appears to be greater when the hides are first brought ashore than afterwards.

The same thing has been observed at Bradford, where a peculiar *Woolsorters' Disease* has for many years prevailed, and this has recently been shown to be identical with anthrax. The source of infection in that case is chiefly "Van mohair," a material which contains much putrid matter and many "fallen fleeces," torn off the bodies of dead animals. Dr Bell, who gave an excellent account of the affection in the 'Lancet' for 1880, remarked that the men who are attacked are chiefly the "bagmen"—that is, those who open the bags in which the hair is packed, shake it out, and sort it into different qualities. The reason is, no doubt, that the virus is in a dried state, and that as soon as it is disturbed it diffuses itself in the air and is inhaled into the lungs. Perhaps it may actually have multiplied itself during the transmission of the bags from Asia Minor; for, according to Dr Bell, the hairs are not known to communicate disease to persons who handle them in the country where they are grown. Indeed, no form of anthrax so severe as the Woolsorters' Disease had hitherto been described as occurring in man. The work of sorting is said to be free from danger

if the contents of the bags are first washed or even moistened with water.*

Other occupations which sometimes lead to infection with anthrax are the picking of Russian horsehair (as reported by Dr Russell, of Glasgow, in 1879), paper-making, and the manufacture of coarse woollen hats.

Varieties of human anthrax.—There are several forms of this disease in man, and they are not identical with those met with in animals.

1. *Malignant pustule* or *charbon* is the name by which the most common form has long been known. This consists in the formation of a vesicle, seated upon a more or less brawny base. Being usually produced by the inoculation of a scratch or slight sore, it occurs chiefly on the face, especially the cheek, and also on the neck, the forearm, or some other exposed part.

There is first a period of incubation, lasting generally several days, often ten, but sometimes only a few hours. A slight pricking or burning sensation is then felt, which often leads the patient to think that he has just been stung by an insect. A papule quickly appears, and soon passes into a transparent vesicle, which may reach a considerable size. This ruptures and dries up into a dark-coloured scab. Round it there sometimes arise smaller vesicles arranged in a ring. Meanwhile the base of the vesicle becomes indurated, and a red or purple areola is developed round it. A brawny œdema quickly spreads over the adjacent parts, affecting perhaps the whole of one arm, or of one side of the neck. Sometimes inflammation of lymphatic vessels occurs, and the corresponding glands become swollen.

During the early part of this morbid process the health remains unaffected. The patient may continue at his work, and at most complains of slight malaise and of febrile disturbance. But after about forty-eight hours severe pyrexia sets in, often attended by delirium, prostration, diarrhœa, sweating, and acute pains in the limbs; and death, preceded by a state of collapse, may occur between the fifth and the eighth days. In one case which occurred at Guy's Hospital, the original vesicle had been situated an inch and a half behind the left angle of the lower jaw, and respiration became so difficult towards the last that recourse was had to tracheotomy. We found after death that brawny infiltration had extended deeply to the fauces, so that the entrance of the larynx and its interior were greatly swollen. In other instances the immediate cause of death is septicæmia or coexistent anthrax of the intestine or lungs.

Diagnosis.—The only disease liable to be mistaken for anthrax affecting the skin is that which has been particularly noticed by Sir James Paget under the name of *facial carbuncle.* It presents no definite vesicle or central scab; and in most instances we have found the veins of the face obviously plugged with puriform thrombi, which has not been the case in anthrax.

Bollinger, however, and other writers describe, under the name of *anthrax-œdema*, a modification of the true charbon, in which there is neither vesicle nor eschar, but only a pale yellowish swelling of the subcutaneous tissues. The eyelids are the most frequent seat of this variety.

* See Reports to the Local Government Board by Mr John Spear: 'On Woolsorters' Disease,' 1880, and 'On Anthrax among persons engaged in the London Hide and Skin Trades,' 1883. Also papers by Sanderson ('Journ. R. Agric. Soc.,' vol. xvi, p. 267) and Greenfield (ibid., xvii, 30). That the infection of anthrax is conveyed by the hides is implied by Virgil in the concluding lines of the third Georgic, which stand at the head of this chapter.

One way of arriving at a diagnosis of a suspected case of anthrax is to inoculate a rabbit or a guinea-pig, or even a mouse, with fluid from the part primarily affected, or with the blood. Such small animals commonly die in two or three days, or still more rapidly, with dyspnœa, dilatation of the pupils, and perhaps convulsions. Their blood may then be seen to swarm with bacilli. However, if the experiment of inoculation is followed by a negative result, a negative conclusion is not warranted.

On examination after death the naked-eye appearances are those of an infective fever:—congested lungs, flaccid heart, and more or less ecchymosis or hæmorrhage. As a rule, the spleen is much enlarged and softened, but in a case under the writer's care in August, 1889, which proved fatal after operation on the primary pustule, the spleen was not swollen; but the distinctive microscopic evidence of anthrax-bacilli was present.

Treatment.—The recognition of the ordinary external form of anthrax is of extreme importance, because surgical treatment at an early stage is capable of arresting its progress. The disease is not, indeed, necessarily fatal, even when left to itself. Sometimes the central part of the swelling sloughs out, the surrounding induration subsides, and an ulcer is left which more or less quickly heals. Such a spontaneous cure is very rare. Among nine instances recorded in 1863 by Dr William Budd eight ended fatally. On the Continent it has long been the practice to destroy the local lesion as soon as it is brought under the eye of a surgeon. Bollinger cites the experience of two observers who lost only thirteen cases out of one hundred and forty-two; another had still greater success, since among two hundred and nine patients all but eleven recovered. In 1878 Mr Davies-Colley recorded in the 'British Medical Journal' two cases, in each of which recovery took place after excision of the entire mass of indurated tissue, with the application of chloride of zinc paste to the wound. Contrasting with these is a case which was left alone, and which ended fatally. Several other successful cases at Guy's Hospital have been recorded by the same writer in the 'Med.-Chir. Trans.,' vol. lxv, 1882. Since that date (June, 1882—December, 1889) forty-eight more cases have been admitted to Guy's Hospital; and of the total sixty-five cases of external anthrax forty-three recovered after operation. Two typical cases in butchers during an epidemic of anthrax among cattle were operated on by Dr Pitts, of Chelmsford, and recovered perfectly ('Brit. Med. Journ.,' March, 1887, p. 616).

The rapidity with which the surrounding œdema subsides after the operation is often very striking. It may be effectual even when the case is at an advanced stage, and when severe general symptoms are present. But under such circumstances quinine should be given in large doses, and the patient's strength must be kept up with nourishing food and with stimulants. Carbolic acid should also be administered internally, since its therapeutical value in the lower animals when affected with anthrax appears to be generally admitted.

2. *Intestinal anthrax*, another form of splenic fever, affects the gastro-intestinal mucous membrane. This has been recognised only within the last few years, and chiefly by German pathologists. It is sometimes associated with an external malignant pustule. A case in point, in which Dr Goodhart made an autopsy, occurred at Guy's Hospital in 1877. Otherwise its symptoms seem to be obscure, so that a correct diagnosis is not likely to be made

during life unless the patient is known to have been exposed in some way to the virus of the disease. However, Bollinger gives the following account of the symptoms: the patient first complains of malaise, loss of appetite, pains in the limbs, giddiness, and headache. Then vomiting may set in with diarrhœa, and the evacuations often contain blood. There may be pain in the abdomen, which becomes somewhat tumid. Dyspnœa and lividity appear, with restlessness and excitement, or with stupor. Epileptiform convulsions may occur, the upper limbs may be affected with tetanic spasms, there may be opisthotonos, and the pupils may be widely dilated. The pyrexia is but slight, and death is preceded by extreme collapse. The duration of the disease is usually from two to seven days, but sometimes it is scarcely twenty-four hours.

On *post-mortem* examination the abdominal cavity is found to contain a moderate quantity of serous fluid which is often blood-stained. The lining membrane of the stomach and intestines shows patches of swelling, generally of the size of lentils or coffee beans, but sometimes one or two inches in diameter. These on section are seen to consist of a pink fleshy infiltration of the mucous and submucous tissues, so that the valvulæ conniventes appear firm and prominent; the surface of the affected parts is more or less excoriated and discoloured or covered with an adherent layer of extravasated blood. There are also spots of ecchymosis on both the serous and the mucous aspect of the gastro-intestinal tract. The mesenteric and the lumbar lymph-glands are often greatly enlarged, and of a dark red colour. The mesentery may form a large brawny swelling, and the connective tissue in front of the spine may be infiltrated in a similar manner. The spleen is softened to a pulp, but it is not generally much enlarged. A nodule in the stomach may slough out and repair begin, as in a case recorded by the late Dr Mahomed, in the 'Path. Trans.' for 1883.

Fatality.—Hitherto no instance of recovery from intestinal anthrax has been recorded. Leube has related a case in which the lower lip, the inside of the cheek, and the hard palate presented indurated patches of a bluish-red colour: epistaxis and hæmaturia appeared, but the malady ended favourably in about a fortnight. The patient took fifteen grains of carbolic acid and thirty grains of quinine each day, and the patches in the mouth were cauterised three times daily with carbolic acid. But the diagnosis of anthrax was not established beyond question; for only spores, no bacilli, were found in the blood. (Compare Mr John Poland's case: 'Path. Trans.,' 1886, p. 553.)

3. *Pulmonary anthrax.*—A third form of anthrax affects mainly the thoracic viscera. It has hitherto been recognised chiefly among the wool-sorters of Bradford. After Dr Bell, of that town, had drawn attention to it, Mr Spear and Dr Greenfield investigated it for the Local Government Board. Dr Greenfield's description of it is briefly as follows:—The earliest symptoms are great prostration and a sense of oppression of breathing. Shivering seldom occurs. The respiration is not much accelerated, but it is laboured and difficult, with a feeling of pressure or constriction. There may be more or less abundant bloody expectoration, or none at all. Auscultation seldom reveals anything more than slight rhonchus. The face is sometimes congested, sometimes pale, with a slight cyanotic tint. The extremities are cold and bluish; even in the axilla the temperature may be subnormal; but in the rectum the thermometer may rise to 102° or 103°.

The pulse is rapid and weak and sometimes irregular. There may be nausea and vomiting, but not generally diarrhœa. In many cases the appetite remains good, and digestion seems to be unimpaired. There is sometimes a sort of hysterical condition, or a state of mental anxiety and depression; but other patients have been so unconscious of danger as to refuse to send for medical advice until the last few hours of life. Death may be preceded by delirium, convulsions or coma, or the mind may be clear to the last, and the end come suddenly and unexpectedly. One of Dr Bell's patients lived only seventeen hours after he was first taken ill, and many other cases have terminated fatally in from three to five days. Dr Bell says that those who survive for a week generally recover.

The *post-mortem* appearances vary considerably. Decomposition appears to be somewhat rapid. The lung tissue may either be congested or quite natural. There may be blood-stained secretion in the bronchial tubes, and their mucous membrane may be ecchymosed. Sometimes the pleuræ contain a pint or two of fluid, and the lungs are partially collapsed in consequence. There is often blood-stained serous or gelatinous infiltration of the mediastinal tissues, and the bronchial glands are swollen, softened, and ecchymosed. The pericardium may be marked with petechiæ, and may contain a blood-stained fluid; or a large quantity of blood may be poured out between it and the sternum. Sometimes the pharynx and the adjacent tissues are infiltrated with blood or serum. There may also be ecchymoses in the pia mater, in the kidneys, and elsewhere. It is remarkable that the spleen is hardly, if at all, softened. In prolonged cases hæmorrhagic infarctions may be found in the lungs, attended with slight pleurisy; or there may be patches of broncho-pneumonia.

Obviously there may sometimes be considerable difficulty in distinguishing, by clinical evidence alone, this form of anthrax from a severe attack of ordinary pulmonary inflammation. Indeed, until recently, fatal cases of the Woolsorters' Disease at Bradford were commonly registered under the head of pneumonia, bronchitis, or congestion of the lungs. It can hardly be doubted, as Dr Bell suggests, that a similar affection will hereafter be found to occur in many towns where carpet and blanket wools, dry hairs or furs, are used for manufacturing purposes.

General pathology of anthrax.—Certain points in regard to the distribution of the bacilli in animals or men affected with anthrax have still to be mentioned. They have an important bearing upon the theory of infective maladies in general, because they illustrate what is perhaps a universal law, namely, that the microzymes of contagion multiply locally before they infect the blood to any considerable extent. In the ordinary form of the disease affecting the skin, the bacilli may be found, according to Davaine, about the second or the third day, in clusters embedded in the rete mucosum at the centre of the vesicle. E. Wagner has since found that they are at this time so closely packed in the papillæ of the cutis as to conceal all the tissue elements. Thence they spread both laterally and towards the deeper structures, enter the vessels, and are carried all over the body with the blood. In the gastro-intestinal variety the bacilli infiltrate all the swollen and œdematous tissues, so that Buhl and others described this affection under the name of *mycosis intestinalis* before they recognised that it had any relation to anthrax.

At an early stage of the disease the blood may contain no bacilli.

Therefore, if in a doubtful case one fails to discover them in this fluid, one must not attach much importance to this result. On the other hand, the presence of well-marked rods is conclusive; but it does not seem to be sufficient to find spore-like cocci only, as Leube did in the case referred to above (p. 356). In man, even when a fatal termination is approaching, the bacilli seem to be seldom found in such immense numbers, and so generally distributed in the blood, as they are in animals. Davaine calculated that from eight to ten millions are present in a single drop of a diseased beast's blood. In Buhl's first case of intestinal anthrax they are said to have been present in the blood of the portal vein, but not in that of other vessels. They may often be detected in the substance of the spleen and of the solid tissues generally, and also in the fluid poured out into the serous cavities.

Mr Barker, in a case published in the 'Med.-Chir. Trans.,' vol. lxix, p. 127, found the bacilli most abundant in the rete and the papillary layer of the cutis, and they appear to be long confined to that part.

The best account of the histology of the disease in this country is given by Dr F. C. Turner, in the sixty-fifth volume of the same 'Transactions.'

In anthrax we have a typical example of a specific contagious malady, which is due to the presence of microphytes. All the conditions stated on p. 13 are fulfilled. For the disease is recognisable from its clinical features, and breeds true. The organism is well marked in its microscopical characters, size, and shape, in its reproduction and its cultivation. It exists in the blood and tissues of every case of the disease. It exists nowhere else, for its non-mobility distinguishes it from *Bacillus subtilis*. Lastly, when a "pure cultivation" has been obtained, it can be inoculated, and will reproduce the disease, with fresh broods of organisms in the blood.

Prophylaxis by inoculation of the attenuated virus, though inapplicable as a practical measure for human beings, is of too great theoretic importance to be wholly passed over.

Pasteur ascertained that by repeated cultivations of *Bacillus anthracis* in mutton broth, at a temperature above 104°—110° Fahr., he obtained a modified virus which when inoculated into an animal produced a mild attack of anthrax which protected from future attacks. These results were tried on a large scale at Milan and afterwards at Chartres, and proved brilliantly successful (see a paper by Mr George Fleming, in the 'Nineteenth Century' Magazine for March, 1882). Unfortunately, the result is not always so complete, for even the attenuated virus is occasionally fatal. Moreover, the Algerian breed of sheep appears to be insusceptible of the same protection, and in Hungary the results were much less successful than in France. See an excellent abstract by Dr Dawson Williams of Pasteur's and other methods of attenuation, and of Koch's criticism thereon ('Microparasites in Disease,' N. Syd. Soc., p. 560). Dr Roy found in Buenos Ayres that the Viscacha (*Lagostomus trichodactylus*), a rodent allied to the chinchilla, is capable of receiving the disease, and that anthrax thence transferred by inoculation to cattle is both mild and protective, at least for a considerable time— so that the analogy to smallpox and cow-pox is very close.

GLANDERS.*—From an early period in the present century it has been known that those whose occupation brings them into contact with horses sometimes become affected with a disease to which these animals are liable. The disease in question was described as far back as the fourth century B.C. under the names μᾶλις and *malleus*. In England, writers on veterinary medicine have been accustomed to distinguish two varieties, "glanders" and "farcy," the former of which is characterised by a morbid state of the nasal mucous membrane, the latter by the formation of nodules and abscesses in and beneath the skin, and by indolent inflammation of the lymph-glands and lymphatics, attended with swelling (or "farcy buds") at the valves. The first case in the human subject which was correctly interpreted in this country was recorded in 1821 by Mr Muscroft, of Pontefract. In 1830, Dr Elliotson drew the attention of the Royal Medical and Chirurgical Society to the disease, and afterwards proposed to call it *Equinia*. According to Virchow, the derivation of "glanders" is from *morbus glandulosus*, and the equivalent German word *Drüse* is still in use for one of its forms.

Conveyance of contagion.—As a rule, the virus of glanders is directly introduced into a wound or sore, or fissure in the skin, especially of the face or of one of the hands. A horse-slaughterer who died in Guy's Hospital in 1866, appeared to have poisoned a slight cut on the lip which had been made by a barber in shaving him. Injuries to the hand in skinning dead horses, or in dissecting them, have sometimes been the starting-point of the disease. It has also been transmitted by a bite from a glandered animal, probably through the saliva. Or a diseased horse in sneezing may propel a drop of muco-purulent secretion from its nose directly into the eye, or the nose, or the open mouth of anyone standing near it. The contagion remains active in a dried state for a long time, for horses in a particular stable have been attacked many months after the occurrence of a case. Probably it is sometimes deposited upon the straw in a stall, and a groom may disturb the dried particles and cause them to float off into the air so as to infect him with the disease. However, the Messrs Gamgee, in Dr Reynolds' 'System,' express doubts on this point.

According to Bollinger, who describes glanders in 'Ziemssen's Handbuch,' it may be communicated by eating the flesh of a glandered animal, at least in a raw state; he says that lions in menageries often become diseased in this way. Decroix, indeed, is stated to have repeatedly eaten such flesh uncooked, without injury; but it must be borne in mind that in all probability comparatively few persons are susceptible of the virus of glanders. At any rate the disease in man has always been exceedingly rare, even in countries where (as in France during the first half of this century) it has committed terrible ravages among horses. When it affects human beings, it is capable of spreading from one individual to another. Dr Elliotson mentions in the 'Lancet' for 1838 that a laundress who washed the clothes of one of his patients contracted it. In at least one case, infection has taken place through a cut received in examining the body of a person who had died of the disease. It is also inoculable from man to the lower animals; goats and rabbits are said by Bollinger to be the most suitable subjects for experiment. Oxen are stated not to be susceptible, but, next to horses, it is especially apt to affect asses and mules. It is seen in hot as well as in cold climates.

* *Synonyms.*—Equinia—Farcy—μᾶλις, Malleus *v.* Maliasmus.—*Fr.* La Morve, Le Farcin *Germ.* Rotzkrankheit, Wurmkrankheit.

A point of some importance is that grooms are sometimes attacked with glanders when they are not aware that any of their horses have been diseased. Bollinger seems to have satisfactorily explained this, by showing that in the horse glanders sometimes fails to present its more characteristic symptoms and attacks the lungs and the air-passages only.

Bacillus.—Bollinger failed to find bacteria in careful examinations of the fresh blood of glandered animals and of fresh nodules from their bodies. Gerlach stated that the virus is not destroyed by putrefaction. Löffler has since ascertained the constant presence of minute rod-shaped organisms in the "farcy buds," lungs, and spleen of animals dying of glanders. He has succeeded in growing this bacillus, and inoculation with the pure cultivation has reproduced the disease in horses or asses, and also in guinea-pigs, rabbits, and mice. His results agree with those of Schütz, Bouchard, and other observers, and are now generally accepted.*

Glanders in man.—The disease occurs in two forms in the human subject, of which one is termed acute and the other chronic.

1. In *acute glanders* the patient is first attacked with malaise, headache, and pains in the limbs. There is often no initial rigor, and for a time there may be no marked pyrexia. At this stage the disease is generally mistaken for acute rheumatism or for enteric fever. But if a wound or scratch has been infected with the virus, the part commonly becomes red, swollen, and very painful; and an erysipelatoid inflammation may diffuse itself over a wide area, affecting, for example, the whole side of the face, or the hands, and part of the forearm. In such cases the diagnosis generally inclines towards septicæmia or pyæmia from a poisoned wound. In other instances, as in that of a man who died in Guy's Hospital in 1863, the first complaint is of pain in the side with dyspnœa, so that acute pleuro-pneumonia is suspected.

Presently symptoms appear which to an experienced eye reveal the nature of the disease. One of these is an *eruption*. Upon the limbs and the body there arise papules, which rapidly pass into flat vesicles and then into bullæ or pustules, attaining the size of peas or even of sixpenny-pieces. They become depressed in the centre, and rupture, allowing a thin purulent fluid to escape, which is often blood-stained. With regard to their histology, von Wyss has ascertained that the papulation begins as a local inflammatory change in the papillary layer of the cutis. When an incision is made through a pustule after the patient's death, its floor is found to consist of an ashen-grey, infiltrated layer. The eruption sometimes appears within twenty-four or forty-eight hours after the patient is first taken ill, sometimes not for a week, or even longer. When present it is characteristic of glanders, although it might be mistaken at an early stage for small-pox or chicken-pox, and perhaps later on for pemphigus. Generally there is mixed with it an affection which may be taken as the representative of "farcy" in horses. This consists in the formation of hard painful lumps or swellings in the subcutaneous tissues and muscles; they more or less rapidly suppurate, and if they are incised they may ulcerate, so as to expose tendons or bones beneath. It is curious, however, that in most cases the lymph-glands fail to become enlarged. A marked instance to the contrary is recorded by Travers in his work on 'Constitutional Irritation.' Not only

* 'Deutsche med. Wochensch.,' 1882 and 1883; 'Revue Médicale Française,' Dec., 1883; 'Microparasites in Disease,' New Syd. Soc., p. 387, and pl. vi. Klein ('Micro-organisms and Disease,' 3rd ed., p. 128), and Payne ('Pathology,' p. 667, with fig. after Flügge).

was there suppuration of the glands of the arm originally affected, but those at each angle of the lower jaw and in the groin are also said to have been swollen. The joints in glanders not infrequently become inflamed, and pus is effused into them.

The other characteristic symptom is an affection of the mucous membrane of the nose and of adjacent parts (*oxæna*), representing what in horses is termed "glanders" in the narrower meaning of the term. First a thin whitish mucus runs from one or both nostrils; afterwards it becomes purulent, blood-stained, and fœtid. The nose itself now becomes swollen, red, and very painful, and inflammation may spread from it towards the forehead or over the cheeks. If an opportunity arises of examining the parts after death, the lining of the nasal passages is found to be ulcerated, and the septum may even be necrosed. It is to be observed that in the human subject a discharge from the nose is by no means always present in glanders; Hauff observed it in only thirty out of seventy cases which he collected. It is often not an early symptom, but appears in the second or the third week. Thus, during the first days of a doubtful case, the fact that the nose is healthy must never exclude the diagnosis of glanders.

Other mucous membranes are also affected. The conjunctivæ may be severely inflamed, and the eyelids may become greatly swollen. Virchow relates a case which came under von Graefe as one of acute exophthalmos, and its real nature was not suspected until after the autopsy. Sores may form in the mouth, and the gums may become spongy. The pharynx and the palate may ulcerate or become covered with a kind of false membrane. Sometimes ulcers form in the larynx, producing hoarseness, and an œdematous laryngitis may set in, so that tracheotomy may be required. Symptoms of bronchial or of intestinal catarrh may be present. Pustules and sores, which might easily be supposed to be chancrous, are said by Virchow to occur on the glans penis.

The general condition of the patient becomes worse from day to day. The pulse is generally much accelerated, but sometimes it remains slow, the temperature rises irregularly until it may reach 104°; the tongue becomes dry and brown; albumen appears in the urine, and sometimes leucin and tyrosin. Delirium and sleeplessness pass into stupor and coma, and finally collapse, with involuntary escape of the urine and fæces. Death usually occurs towards the end of the second, or in the third week. Sometimes the disease has ended fatally within a week, or even in three or four days, sometimes not for four weeks. Bollinger gives one case of recovery among thirty-eight which he collected.

All that can be done in the way of *treatment* is to sustain the patient's strength with quinine, tincture of iron, nourishing food, and stimulants. The pustules should be opened and the nostrils cleansed by syringing them out with some antiseptic solution.

2. *Chronic glanders* is much more insidious. It is often characterised by the formation of intractable ulcers with thick livid edges. In the museum of Guy's Hospital we have two models of such ulcers, the part affected being in one case the back of the hand, while in the other case there are separate sores upon the forehead, the lobule of the ear, and the side of the face. In other instances, abscesses form about the joints and give rise to fistulous sores; or inflammatory swellings appear on the limbs, beneath the skin, or in the muscles. Or, again, there may be an eruption of pustules like those which are seen in acute glanders, but more slowly developed.

The nose often remains free, but sometimes there is an erysipelatoid redness of the skin or a fœtid purulent discharge from the mucous surface, beginning perhaps after two or three months have passed. Bollinger says that the root of the nose may even become gangrenous. The nostrils are often blocked with dark-coloured crusts. Such an affection is very apt to be regarded as syphilitic, or to be classed under the vague title of ozæna. It is of great importance to remember that the diagnosis may be cleared up by inoculating a goat or a rabbit with some of the discharge. This practice was adopted in some of the earliest cases of glanders that are known to have been observed in this country, those which were recorded by Travers. Bollinger gives details of two such experiments which he performed with matter taken from horses; the inoculated animals, which lived two or three months, showed characteristic symptoms and lesions. In a case at Guy's Hospital in 1866, the late Mr Poland introduced pus from the patient's face beneath the skin of the shoulder and set up pustules there, but probably this result was not of diagnostic significance. Virchow mentions that at Würzburg a man was for six months in the hospital on account of refractory sores upon the limbs. At the autopsy lesions characteristic of glanders were discovered. It was not then known that the disease existed in the neighbourhood, but inquiries were set on foot and led to the discovery of an epizootic prevailing over a wide area among the horses used for towing barges on the River Main.

In some cases the chief symptoms of chronic glanders are cough with sanguineous expectoration, hoarseness, pyrexia, and emaciation, so that phthisis may be suspected.

The average duration of chronic glanders was found by Bollinger to be four months; sometimes it was not more than two or three months. It may end by passing into the acute form of the disease. Among thirty-four cases which he collected from various sources, including many of slight severity, there were seventeen recoveries. As might have been anticipated, the convalescence is generally very slow and is sometimes incomplete. He was himself acquainted with a veterinary surgeon who, at the end of eleven years, was still cachectic, and was troubled with cough and other symptoms due to the presence of cicatrices in the larynx and in the nose. But he says that some patients, after a severe illness lasting for months, get quickly well and regain the flesh that they have lost.

The means of *diagnosis* now adopted in cavalry stables is to inoculate an ass with the mucus from the nostrils of a horse suspected to be glandered.

As to *treatment* of chronic glanders, Bollinger thinks that carbolic acid and iodide of potassium are the internal medicines most likely to be useful; the Messrs Gamgee speak of arsenic in combination with strychnia as having sometimes exerted a remarkable influence. Ulceration of the interior of the nose should be treated with injections of creasote water, or a solution of carbolic acid, and the application of nitrate of silver or tincture of iodine may be of service.

Morbid anatomy of glanders.—Many of the *internal lesions* which are found in cases of glanders in man appear to be the result of pyæmia or septicæmia, which often arises secondarily, just as it does in erysipelas; but nodules and more or less extensive patches of catarrhal pneumonia, which have no pyæmic characters, are also seen. Virchow placed glanders, in association with syphilis and lupus, among the "granulation tumours." But he himself states that in the human subject the process concerned in the formation of the pus-

tules and abscesses has little to distinguish it from a simple inflammation. In animals both he and Bollinger describe the affection of the nasal mucous membrane as beginning with the development of minute miliary papules, and in the lungs they speak of nodules of various sizes, some almost exactly like tubercles, others as large as peas, or even as walnuts. In man, Virchow says that on careful examination, characteristic small yellow bodies may be seen in the mucous membrane of the nose, of the frontal sinuses, and even of the larynx and of the trachea. In von Graefe's case he detected them in the choroid of the eye. Von Wyss has since observed them in the gastric mucous membrane. It is interesting to find in one of Elliotson's cases, recorded in the 'Med.-Chir. Trans.' for 1833, a description of similar appearances. "On cutting into the various tumefactions on the head, trunk, and extremities, they were found to be full of pus, underneath which, in many, a number of small white granules were seen, and others, in several instances, were closely attached to the periosteum and perichondrium. The frontal sinuses contained a jelly-like mucus, and a number of similar granules, and on the septum narium was one ulcer exactly like those I have seen in the nostrils of glandered horses, and upon it lay a cluster of granules. Two of these large white circular elevations were found immediately below the sacculi laryngis; Mr Youatt, who was present, called them true glandrous chancres. About an inch below the valve of the colon, for three inches in extent, upon the whole of the surface, were white granules exactly like those in other parts."

In a case which occurred at the Middlesex Hospital in 1872, and which is recorded in the 'Med. Times and Gaz.' for that year, Dr Coupland discovered an acute inflammation of the spinal cord.

FOOT-AND-MOUTH DISEASE.*—In striking contrast with the dangerous epizootic diseases hitherto described is one which in cattle seldom causes more than a transitory illness, and which when communicated to man generally produces but trifling effects. It is termed the "Foot-and-Mouth Disease." Some writers have unwisely appropriated to it the mediæval name of *murrain*, which is familiar from its being used in the English translation of the Bible. On the Continent the complaint in question has been known for centuries, but it is said to have been first introduced into England in 1839. In 1869 it prevailed here extensively, and in 1871 it is believed to have affected as many as 700,000 animals. It occurs chiefly in cattle and in sheep; pigs are also liable to it, but probably only as the result of infection by feeding upon the milk of diseased cows. It is very rarely seen in horses.

In cattle, the foot-and-mouth disease is attended with a moderate degree of pyrexia. One of the most marked symptoms is the formation of vesicles and bullæ upon the mucous membrane of the mouth, including the lips and the tongue; these parts also become swollen, and there is a dribbling of saliva. The vesicles soon break, and their floors become covered with a thick grey layer. A somewhat similar eruption appears upon the feet, round the borders of the hoofs, and in their clefts. The vesicles then pass into pustules and dry up into crusts. They give the animal pain in walking or standing, so that it generally remains lying down. Another seat for the vesicles is upon the udder and the teats, which may in consequence become raw and excoriated. But within twelve or fourteen days all the

* *Synonyms.*—Aphthous Fever—Aphtha Epizootica—Glossanthrax—Eczema Epizooticum.

effects of the complaint pass off. It almost always ends in recovery, except in calves. Of these from 50 to 75 per cent. die, probably because the milk yielded by their mothers (when they also are affected) has an irritant action upon the alimentary canal, besides conveying the specific virus.

The *contagium* appears to reside in the fluid contained in the vesicles. By cultivating in agar-agar, in broth, and in milk (which it turns acid, but does not curdle), Dr Klein has succeeded in isolating an apparently distinct micrococcus.

The disease in man.—One may well be surprised that, if foot-and-mouth disease is capable of transmission to man at all, it should not be frequently transmitted. Yet in the 'Brit. Med. Journal' for 1867 will be found a list of only twenty-two notices of such an occurrence, which were all that Prof. McBride could find recorded during the previous thirty years; and most of these were taken, not from medical journals, but from the 'Veterinary Review.' It might therefore be supposed that human beings are but little susceptible to it. But, if so, it is curious that two foreign observers, Hertwig and Jacob, should each have readily succeeded in infecting himself experimentally by drinking the milk of diseased animals.

Conveyance.—There are two ways in which the complaint may be communicated to man. One is by the direct *inoculation* of the specific virus into a crack or sore place, generally on the hand or on a finger. This is especially apt to happen to a person engaged in milking a cow with the eruption upon the teats, but sometimes saliva or fluid from the mouth conveys the contagion to a veterinary surgeon who is attending to the sores there; and a butcher is said to have taken it by holding his knife between his lips while dressing an infected carcass.

The other way is by *drinking the milk* of a diseased cow. This is far more important, not only because it concerns children, who suffer much more than adults, but also because it is very likely to be overlooked, at least by persons who are not conversant with the symptoms observed under such circumstances. As to the characters of the milk which is yielded by cows suffering from the foot-and-mouth disease, there have been some discrepancies of statement. Sometimes it is offensive to the smell and the taste, and it may even be mixed with blood or pus in considerable quantity; but this seems to be only when the teats are severely excoriated, or when the mammary glands themselves have become inflamed as the result of an undue retention of their secretion. In other cases it is less obviously altered; and then one of its most marked peculiarities is a tendency to coagulate when boiled, or even at a much lower temperature, forming innumerable little flocculent masses, which float in a bluish whey. Sometimes it seems to have a yellowish tint, and when examined microscopically displays granular cells like those of the colostrum. But sometimes it is said to have a perfectly natural appearance. It seems generally to be diminished in quantity by about one half. There is no doubt that it is very often drunk with impunity, not only by adults, but even by children. In any case boiling may be assumed to render it innocuous.

Course.—The *incubation* of the "foot-and-mouth" disease in man is said to be from three to five days. At the end of this time slight pyrexia arises, with loss of appetite. A sensation of dryness and heat in the mouth is then noticed, and vesicles quickly appear upon the inside of the lips, on the tongue, and sometimes upon the fauces and hard palate. They reach the size of peas, their contents become opaque and yellowish, and in from

one to three days they break, forming shallow, dark-red ulcers. There is some pain, which is increased by mastication, by swallowing, and by talking. The lips become swollen, and mucus and saliva are poured out in excess. In a case related by Mr Briscoe, of Chippenham, in the 'Brit. Med. Jour.' for 1872, the tongue swelled until it protruded for two inches and a half outside the mouth, and it was so firmly wedged between the teeth that for thirty-six days the patient took no food except milk; there was great dyspnœa, and suffocation appeared at one time imminent; sloughs peeled off the tongue, and the discharge became very fœtid. Such a condition, however, is altogether exceptional. There is often slight disorder of the digestive organs, indicated by diarrhœa and abdominal pain.

In some patients an eruption appears upon the fingers, especially round the nails. It consists of small clear vesicles, which pass into pustules, and sometimes run together. It very rarely happens that the inflammation is sufficiently intense to cause shedding of the nails. The feet are seldom affected, but sometimes vesicles have been observed between the toes. Mr Amyot ('Med. Times and Gaz.,' 1871) mentions the case of a woman in whom the feet "became hot and covered with painful tubercles." It is said that the female breasts have occasionally presented tubercles, and even the face and other parts of the body. In Mr Hislop's case ('Ed. Med. Jour.,' 1863), in which there was a red scaly rash upon a farmer's forehead, and upon the body and lower limbs of his wife, cured by bichloride of mercury and iodide of potassium, one may venture to doubt whether foot-and-mouth disease was really present, or syphilis.

Diagnosis.—The eruptions, however, for which the foot-and-mouth disease seems most likely to be mistaken are varicella and slight smallpox. The affection of the lips and tongue might be set down as a simple aphthous stomatitis. Indeed, it is not impossible that a slight catarrhal inflammation of the mouth, with a little soreness of throat, may be a far more common result of infection by diseased milk in infants than has hitherto been suspected. A doubtful case might always be cleared up by the inoculation of a sheep which has not had the disorder already.

Prognosis.—The duration of the foot-and-mouth disease in man is usually from ten to fourteen days, but sometimes not more than a week. A case fatal by septicæmia has been recorded, but with that exception death has occurred only in very young children.

The sole *treatment* required is the application of a solution of borax to the mouth, or of the solid nitrate of silver to any painful ulcers; the eruption on the fingers may be dealt with like a mild eczema.

ACTINOMYCOSIS.—Of late years a fourth contagious disease of the lower animals has been recognised in man.

The malady was long known among cattle as a suppurative inflammation, usually affecting the tongue or jaw, occasionally the skin or the lungs (cf. Rivolta, of Pisa, in 'Virchow's Archiv,' 1875, vol. 88, p. 309). It was called "wooden-tongue" by the herdsmen, scrofula and osteosarcoma by veterinary surgeons. The vegetable parasite which gives rise to it was first described in cattle by Bollinger in 1877, and named Actinomyces (*i. e.* ray-fungus).

In man it has probably been often mistaken for tubercular nodules and caseous inflammation or sarcomata, in the liver or lungs.

The first two undoubted cases published were by Dr James Israel, of Berlin,

in 1878,* one a man of thirty-nine, with multiple abscesses and serous inflammations, and the other a man of thirty-six, with a submaxillary abscess, who recovered. In both the characteristic nodules and the "club-shaped or pear-shaped bodies" are unmistakable (pl. i, fig. 2; iii, fig. 5). In his article he publishes notes of a third case observed by Professor von Langenbeck at Kiel in 1845 of vertebral caries in a man; and the drawings then made and reproduced by Israel (pl. iii, fig. 9, *a* and *c*), prove that it was Actinomycosis. Ponfick first recognised these *Mycoses* to be the Actinomyces discovered in cattle by Bollinger. He has since published a monograph on the subject ('Die Actinomycose des Menschen,' 1882).

A remarkable case was brought before the Hunterian Society by Dr F. C. Turner (March, 1887). Here it was combined with true tubercular disease, probably of independent origin.

Numerous cases in the jaws and tongue of cattle are in the Museum of the Royal College of Surgeons (Nos. 2254, *b*, *c*, &c., and 2274, *b*, &c.).

The remarkable peculiarity of the disease is that each inflammatory nodule or abscess has in its centre a parasitic fungous growth, which varies from the 100th to the 10th of an inch in diameter. In one of the earlier cases observed in this country a section from the morbid tissues of the tongue of an ox was shown the writer by Professor Roy at the Brown Institute. The large size, glittering aspect, globular shape, and surrounding mass of radiating club-shaped structures distinguished the organism at once from any known morbid product, and suggested the presence of lime salts or some other crystalline material. This, however, is not the case.†

Actinomyces, as the fungus was named by the botanist Hartz in allusion to its radiating gonidia, is not one of the group of Schizomycetes to which the micrococci, sarcinæ, bacteria, bacilli, and vibriones of anthrax, glanders, and other specific contagious febrile diseases belong. It is apparently one of the Hyphomycetes, the group to which moulds like *Penicillium glaucum* and *Mucor* belong. The centre of each minute yellowish nodule consists of an immense number of interlacing threads, apparently mycelium.

The mode of invasion of Actinomycosis is unknown. It is remarkable that it has never been traced to direct contagion from cattle, and it is possible that both cattle and man derive it from some vegetable source, and that it is introduced through carious teeth, or directly from the mouth, intestines, or bronchi.

When established in a living tissue each mass reproduces by gemmation, and so spreads in its neighbourhood. As it grows, a zone forms around it of large nucleated cells, not unlike giant-cells in appearance. They are surrounded by leucocytes (inflammatory or exudation corpuscles), and these again, in the larger and older specimens, by a capsule of spindle-cells or fibrous tissue. The inflammatory nodules thus formed coalesce and gradually form large tumours. While still scattered and small in the lungs they much resemble tubercles. The characteristic rosettes of club-

* 'Virchow's Archiv,' 1878, vol. lxxiv, p. 15, "Neue Beobachtungen auf dem Gebiete der Mykosen des Menschen"—'Klin. Beitr. zur Kenntniss der Actinomycose des Menschen,' Berlin, 1885. Translated in abstract for the New Sydenham Soc. in their vol. on 'Microparasites in Disease,' by Dr Hime, of Bradford, 1886.

† See Israel's original paper above quoted, where it is stated that Dr Ferd. Cohn, who recognised the fungus, at first thought them to be fat crystals; also the discussion on Dr John Harley's case of so-called "Actinomycosis of the Liver," 'Med.-Chir. Trans.,' 1886, p. 135, and 'Proc.,' N.S. vol. ii, p. 20.

shaped glistening cylinders stain strongly with eosin, or magenta and picric acid.

As we should expect from the botanical character of the parasite, it does not infect the blood, lymph, and tissues like bacteria and their allies, but acts as a local irritant, spreading slowly, and limited in its action to the tissues and organs successively affected. Pathologically, therefore, actinomycosis does not belong to the same group of acute febrile infective diseases as anthrax and glanders. It belongs to a group well represented in the pathology of the lower animals, of which the *pébrine* of silkworms is a well-known example. The *Saprolegnia*, which causes salmon disease, is another. Grobe, Loch, and other pathologists have produced artificial "mycosis" of the kidneys and other viscera in the rabbit by injection of the spores of *Aspergillus*. In Favus and Ringworm, as in Thrush, the parasite is a fungus; but, owing to its not penetrating the skin or mucous membrane, its effects are only superficial. It is possible, however, that cases may hereafter be recognised in man of other internal diseases due to invasion of parasitic fungi, and therefore analogous to actinomycosis.*

The fungus is difficult to cultivate out of the body. Recently, however, Boström is said to have succeeded, and his results throw doubt on its position among Hyphomycetes.† Inoculation has generally failed, but Ponfick has succeeded in reproducing the disease in calves.

There are nearly a hundred cases (some not certainly genuine‡) now recorded of this disease in man. Usually, as in cattle, it affects the mouth and jaw, sometimes the bronchi and lungs or the intestines and peritoneum, and sometimes the liver only. Two of the last group were described by Mr Shattock ('Path. Trans.,' 1885), one of them an old specimen from the Museum of St. Thomas's Hospital, and Dr John Harley's case is a third.

The fungus differs considerably in some recorded cases in man from the characters described in cattle. Whether these are specific differences or depend on a stage of development or some other modifying cause remains to be seen. (Compare Dr Theodore Acland's figures, 'Path. Trans.,' 1886, pl. xxv, with those in Dr Harley's case, and both with Israel's, Ponfick's, and Crookshank's drawings.)

When the tumours or abscesses are accessible to surgical treatment, actinomycosis may be cured both in animals and in man. Hence the best prognosis is when the disease affects the tongue, jaws, or neck, and the worst when it affects the lungs or the liver.

In a remarkable case, seen by the writer with Dr Ransom, of Nottingham, the patient, a strong and healthy man, of about fifty, was attacked with what appeared to be typhlitis followed by extensive suppuration in the subperitoneal tissues, and at last by abscess of the liver. The correct diagnosis was made by Dr Ransom discovering in the pus discharged after incision minute brown granules, just visible to the naked eye, which collected at the bottom of a glass, and showed the characteristic club-shaped structures above described.

* In Dr Paltauf's fatal case of *Mycosis mucorina* in man, the fungus invaded the body through the intestines, and led to abscesses in the lungs, brain, and other organs (see 'Virchow's Archiv,' vol. cii, with references to fungi in the air-passages, &c., p. 543).

‡ One, for instance, tabulated by Israel, is Mr Treves's "Case of Supposed Actinomycosis" (as he rightly called it), which proved to be large-celled alveolar sarcoma, 'Path. Trans.,' 1884, p. 356.

HYDROPHOBIA.*—From the time of Aristotle it has been known that dogs are liable to a fatal disease which they transmit by their bite; and this disease, when occurring in man, was called "Hydrophobia," from the dread of water, which is one of its chief symptoms. In the lower animals, however, that very symptom is absent. Although the symptoms of this terrible disease are those of paroxysmal nervous convulsions, its natural place is in association with Glanders, Anthrax, and other specific diseases, transferred from animals to man.

Incubation.—Judging from what we know of the inoculation of poisons in general, we should have expected that the introduction of the virus of rabies through a bite would have produced its effect after a definite interval, and without much delay. The contrary, however, is the case. After the healing of the wound, which takes place naturally and quickly, there occurs a period of incubation, which is often prolonged beyond that of all other infective diseases, and which is of uncertain duration, both in the lower animals and in man. Bollinger, in Ziemssen's 'Handbuch,' says that in 60 per cent. of all cases in the human subject it is between eighteen and sixty days, in 6 per cent. between three and eighteen days, and in 34 per cent. longer than sixty days. How protracted it may be we cannot yet positively tell. Instances have been recorded in which three years, five years, even twelve years, were supposed to have elapsed. In 1854 there occurred at Guy's Hospital, in the practice of Dr Hughes, a case in which it was said that five or seven years had passed since the bite. It is possible, however, that in these cases a subsequent infection took place without the patient's knowing it. That this is possible must be admitted; for, on the one hand, the origin of hydrophobia cannot always be traced at all, although it is most unlikely that it ever arises *de novo;* and, on the other hand, Mr Youatt succeeded in tracing certain cases to sources that might very easily have been overlooked; one, in a man, to his having tried to untie with his teeth a knot in a cord by which a rabid dog had been confined; and another, in a woman, to her having used her teeth to press down the seam in mending a tear in her dress caused by the bite of a rabid animal.

The following are the results of inquiries as to the period between the bite and the appearance of symptoms in cases at Guy's Hospital. Six were published by Dr Bright (1820–30). Seven more were reported by Mr Cooper Forster in the 'Guy's Hospital Reports' for 1866 (Third Series, vol. xii, p. 1). The incubation in these thirteen cases varied between four weeks and eleven months, except one, in which it was supposed to be from five to seven years. In ten cases which have occurred since the publication of that report and the present year (1867–89), collected for this edition by Dr E. W. Goodall, the periods of incubation were nineteen weeks, thirty-five days, thirty-eight days, forty days, nine weeks, nearly twelve weeks, thirteen weeks, and about twelve weeks respectively, and, more doubtfully, four weeks, while in the tenth case (a man aged thirty-six, who died in 1878) no certain evidence could be obtained, either from the patient or his friends, that he had ever been bitten by a dog. No doubt the period of incubation varies more than in other specific diseases, but in the most authentic and well-observed cases it is rarely more than twelve months.

In 132 cases of hydrophobia, selected by the Registrar-General (1886) on account of the circumstances being accurately known, the shortest incuba-

* *Synonyms.*—Rabies canina—Lyssa (λύσσα, raging madness).—Fr. La rage—Germ. Hundswuth, Wasserscheu.

tion was eleven days, in a child bitten by a rabid cat. In 23 cases it was under a month, in 64 between one and two months, in 21 between two and three months, in 124 it was under five months, in 127 under ten months, and in 130 under two years. In one case it was between three and four years and in one other above four years.

The most frequent incubation period is about six weeks. When the infecting wound is on the face the incubation is probably shorter. In children also it is usually shorter than in adults.

Experimental inoculation in dogs, rabbits, and other animals shows, on the whole, shorter periods than when the disease dates from the infliction of a bite by a rabid dog; and when the virus is introduced, not subcutaneously but beneath the dura mater after trephining the skull, the period of incubation is measured by days, a week being a very frequent time.*

Prodroma.—In some cases the earliest indication of the onset of hydrophobia is afforded by an uneasy sensation in the seat of the bite, which becomes painful, or tingles, or itches, or feels cold; sometimes the cicatrix itself may be seen to be reddened, livid, or swollen; perhaps it may open afresh, or a papular eruption may appear around it. The pain or other morbid sensation extends upwards along the nerves; from the hand, for example, into the arm and up to the shoulder, as in a coachman whose case is recorded by Sir Thomas Watson. In a gentleman who came under the care of Mr Cooper Forster in 1866 the pain was of extraordinary severity; it came on in paroxysms, obliging him to stop suddenly in the street, and to cry out; it was not referred to the course of any particular nerve. There was in that instance no redness or tenderness of the cicatrix. The arm, however, felt much colder than the other one. He had been bitten eleven months previously; in the intervening period of time he had three or four times complained of pain up the arm and twitchings in the hand.

There is probably no tendency to lymphatic inflammation beyond what might arise after any other injury of equal severity. Watson cites two instances of such an occurrence; but in one of them, at any rate, the red lines which extended up the patient's arm were probably due to the caustic which had been applied.

Other early symptoms are a peculiar restlessness, irritability, and depression of spirits. The patient suffers from nausea and loss of appetite; he complains of headache, is sleepless, and has a distressing sense of apprehension. It is curious that he often says nothing about having been bitten, and will even vehemently deny it. And yet he may make other remarks which show that his mind is dwelling on the subject, and that he is trying to persuade himself that he need not be afraid. The most characteristic symptom is a repugnance to fluid, which may show itself in various ways. Sometimes there is a little difficulty in swallowing, from a feeling of tightness about the throat. Sir Thomas Watson's patient, the coachman, refrained on account of a similar sensation from sponging himself as usual with cold water, though he remarked that he "could not think how he could be so silly." Often the breathing is interrupted by frequent sighs, which may stop the man in the middle of a sentence.

Symptoms when developed.—The above prodromal or early stage generally lasts from one to three days, but sometimes it is altogether absent. In

* See "Horsley's Lecture before the Epidemiological Society," Feb. 13th, 1889 ('Brit. Med. Journ.,' p. 342).

either case, the full development of the disease is ushered in by the sudden occurrence of violent convulsive paroxysms, affecting the muscles of deglutition and those of respiration, and repeated at more or less frequent intervals. They are brought on by a variety of causes. The attempt to drink almost always instantly precipitates one; the sight of fluid in a basin often has a similar effect. Watson mentions a case in which the patient was thrown into a violent state of agitation by hearing a dresser, who was sitting up with him, make water. The least draught of air, the waving of a mirror before the eyes, the opening or shutting of a door, the slightest touch upon the skin, the attempt to comb the hair, may each excite an attack. Sometimes the patient succeeds in gulping down a little fluid by carrying it to his mouth with the eyes shut, or he may insist on the withdrawal of the bystanders as enabling him to swallow better. Watson saw one man who so dreaded anyone's breath on his face that he would not converse with the apothecary of the hospital except in such a position that the chin of each of them rested on the other's shoulder. The seizures often consist of a series of shuddering or sobbing movements, more or less like those which occur when one steps into a cold bath. Sometimes, however, they are attended with tonic spasms of the cervical muscles, the sterno-mastoidei (for example) starting forwards strongly.

The following description of the more violent paroxysms was drawn up by Dr Bushell, now Physician to the British Legation at Pekin, from a case which occurred while he was dresser to Mr Cooper Forster. "At the onset of a severe spasm the patient springs up in bed, and puts his hands furiously to his throat, as if to tear something away; the head is thrown violently back, the mouth is opened, and the eyeballs are protruded; then he makes several expiratory efforts, sometimes with a shrill screaming cry; the head is thrown violently from side to side; the hands are tossed wildly about, beating his chest, and striking anything that is near." Sometimes the jaws are sharply brought together, so that one can hardly tell whether the patient is not trying to bite those about him. The production of a barking noise, like that of a dog, appears to be fabulous. Bollinger denies that trismus ever occurs, or a general tonic spasm like that which characterises tetanus. Nor is there an authentic case in which complete opisthotonos was present, although Dr. John Ogle described one in which there was said to be emprosthotonos ('Med.-Chir. Rev.,' 1868). Sometimes these convulsions seem to be spontaneous, but often they can be recognised as reflex spasms from a sensory excitation. The skin is in a state of hyperæsthesia, particularly to effects of temperature.

The duration of the paroxysms is variable. According to Bollinger, they occasionally last from thirty to forty-five minutes. When they are at all protracted, the patient's face and limbs become pale and livid and covered with sweat. The countenance assumes an aspect of terror, and the pupils are widely dilated. The pulse is rapid, the respiration also quickened, irregular, and more or less forced.

The temperature varies greatly. It is usually moderately raised, sometimes normal, and occasionally rises to 103° or even 105°, as in a case noted by Mr Southam, of Manchester ('Brit. Med. Journ.,' 1881, vol. ii, p. 814).

The urine appears to be normal as a rule; sometimes febrile, rarely albuminous. The occasional presence of glycose is perhaps due to inhalation of chloroform.

In women and young children the course of hydrophobia is often com-

paratively mild, although it is even more quickly fatal; this was so in two of Sir Thomas Watson's cases, one in a lady aged thirty-two, the other in a girl only five years old, and also in a little girl who died in Guy's Hospital in 1875. She was so slightly affected that Mr Stocker supposed the case to be one of hysteria. In other instances, however, children affected by hydrophobia exhibit the most frantic mania.

In some very rare instances the paroxysms are said to be altogether absent, so that the patient is able to drink, though with difficulty, throughout the disease. But, as a rule, there is an almost absolute inability to swallow, even during the intervals. The patient, who is much distressed by thirst, may resolutely carry the cup or the glass to his lips, but as soon as a little fluid has entered his mouth it is forcibly ejected, and all the rest is spilt over his clothes. The tongue is said to be generally clean and moist; but the fauces and the palate may be seen to be injected, and their glands are swollen. A viscid saliva which collects in the mouth is a source of great annoyance; it is hawked up with noisy effort, and spat out upon the floor in all directions, or upon the faces and clothes of the nurses.

Another symptom, which is present in certain cases, is priapism, with frequent involuntary emissions. Trousseau observed painful hyperæsthesia of the genital organs.

The mental state, even between the convulsive attacks, is almost always one of great agitation. As the disease advances, the patient often raves at those around him, accusing them of being the cause of his illness, and complaining of their gazing upon his misery. Even if what he says is not nonsense, he generally talks hastily and excitedly. Sometimes he is wildly maniacal, so that he has to be confined in a strait jacket, or to be held down by several powerful men.

Not infrequently death occurs by suffocation in the middle of a paroxysm, and more or less suddenly. The whole *duration of the disease* is seldom a week, and sometimes it terminates within from twelve to forty-eight hours. In eight cases death occurred in twenty-four hours, in eighty-seven between the first and the seventh day, in five on the eighth, and in one case on the ninth, tenth, and twelfth days respectively (Registrar-General's 'Report,' 1886).

Cases which last a week are exceptional; Sir Thomas Watson's coachman did not die until the middle of the seventh day. In that instance the end was very gradual; the pulse grew rapid and weak, the mental powers failed, he lay moaning and tossing from side to side, frothy saliva ran from his mouth, he lost the power of moving his left arm, fluid stools were passed involuntarily, the lower extremities grew cold, and the coldness extended up to the chest. Some patients have towards the last become paraplegic. In the more protracted cases the spasms may cease for some hours before death, the patient be quite calm and able to talk or drink or wash his hands without discomfort, but nevertheless the coldness of his surface, and the absence of pulse at the wrist, show that there is no real improvement.

Contagion from rabies.—Hydrophobia is doubtless caused in all cases by the transference to the patient of the specific virus of rabies; but as to the conditions under which this may occur, many interesting questions arise. Thus it has not yet been finally determined whether the disease is under any conditions communicable from one human being to another. No case is known of the kind, and medical men and nurses always escape, although the poisonous secretion is often ejected upon their clothes and hands and

faces. In former times the dread of catching the disease was so great that the patient was often smothered between feather beds by his relations, or was allowed to bleed to death through an opened vein. Bollinger says that on the military frontier of Austria persons labouring under hydrophobia, or suspected of it, are even now liable to be shot by their neighbours, and that those who have been bitten by rabid dogs sometimes commit suicide.

There is no doubt that the virus resides in the saliva and salivary glands. Magendie long ago produced rabies in dogs by inoculating them with the saliva of hydrophobic patients. Pasteur has now proved that the spinal cord is also the seat of the virus; and that inoculations from it, especially if introduced under the dura mater of a dog, after trephining the skull, will reproduce the disease in dogs and rabbits.

The disease in animals.—Rabies may occur in many kinds of animals besides dogs. It is common in wolves, jackals, and foxes, and the bite of a rabid wolf is notoriously the most dangerous of all. Cats are sometimes affected by it, but far less frequently than dogs. A scratch from a cat is believed to have conveyed it to a child, no doubt from the claws having been impregnated with poisonous saliva. Among herbivora, horses, oxen, goats, sheep, pigs, rabbits, and guinea-pigs are capable of being infected experimentally by inoculation, or if they are bitten by rabid dogs. Mr Youatt recorded a case in which a groom took hydrophobia through a scratch which he received from the tooth of a rabid horse.

Rabies broke out as a destructive epidemic among the fallow-deer at Richmond in 1889, and soon afterwards in the Marquis of Bristol's park. More than 450 died out of a herd of between 600 and 700 in the course of three months.*

A most important question is what indications should lead one to decide, when a person is bitten by a dog, that the animal is rabid. Mr Youatt met with cases in which a dog exhibited no symptom of rabies when it inflicted the fatal bite, though it was soon afterwards attacked. No fewer than eighteen or nineteen instances of this kind have been collected. The simplest way of accounting for them is to suppose that the disease is infective even during its period of incubation, which in dogs is believed to be generally of from three to five weeks' duration, but occasionally to be prolonged over as many months. It is evident, therefore, that when a dog is killed soon after having bitten a human being, one can never be quite sure that hydrophobia may not supervene. The proper course is to keep the animal securely confined for some weeks.

There are two varieties of the disease in dogs; one characterised by maniacal excitement, the other by paralysis of the jaw, so that it hangs down and allows a frothy saliva to run out of the mouth. In each form the bark is altered into what is described as a "hoarse inward sound, dissimilar from its usual tone, and generally terminating with a peculiar howl." Towards the last the hind legs and the loins become paralysed, so that the dog staggers about and falls. The popular distinction between ordinary rabies and "dumb rabies" with paralysis is not without foundation.

One of the earlier symptoms is an extraordinary perversion of the appetite, the animal eating hair, straw, sticks, bits of leather, earth, stones, and other substances, which remain undigested and may be discovered in the stomach after death, mixed with a dirty-brown pulpy fluid. Their pre-

* See Mr Adami's interesting account in the 'Brit. Med. Journ.' for Oct. 12th, 1889.

sence often affords a valuable indirect proof that a dog which has been killed under the suspicion of rabies was really affected with that disease. It has been said that a verdict of acquittal may be given whenever the digested remains of the animal's natural food are found in its stomach and chyme in its small intestine; but of course the disease might even then have been incubating. Change of disposition, snapping, hiding, wandering, are all indications of rabies in a dog.

As already remarked, a dread of water is not a symptom of rabies in any animal except man. "Mad dogs," as they are commonly called, plunge their muzzles into water and lap it up eagerly (for they are very thirsty) although they may not be able to swallow.

Rabies is always fatal in dogs—usually in a week after the symptoms have appeared, occasionally after nine or ten days.

In *rabbits* the symptoms of rabies (transmitted from dogs) are like those of dumb madness, in the absence of excitement and the development of paraplegia, which, as in dogs, takes the form of "acute ascending paralysis." A man who was bitten by a rabid cat in 1886 died under Dr Bristowe in St Thomas's Hospital with symptoms of this kind.

The study of the disease when reproduced by inoculation in animals shows a very similar series of symptoms to those which are characteristic in man. There is first a stage of excitement with visual delusions; then hyperæsthesia with reflex spasms; next the stage of mania, and (particularly in rabbits) paraplegia, corresponding to the "dumb rabies" of dogs; and lastly, death, often by sudden failure of the heart.

Distribution and frequency in man.—At one time hydrophobia was supposed to occur chiefly in temperate climates, but this is not the case.* The only part of the world in which it is as yet unknown is Australia. Like other specific diseases it is often absent from a town for several years together, until some accident introduces it and it becomes epidemic. It has recently been much more common in London than for many years before.

Between 1820 and 1830 six cases of hydrophobia occurred in Guy's Hospital. Two occurred in 1831, one in 1837, and then none for nearly twenty years. In 1856 there was a single case admitted, in 1865 two, and in 1866 the case of a private patient of Mr Forster's was alone recorded. Then again there was a pause for several years, the next case occurring in 1874. In 1875 another was admitted, three in 1877, and one in 1878. After five years' interval there was one case in 1883, two in 1885, and one in 1886. None have been admitted during the last three years (1887–8–9).

For London, the Registrar-General's returns show twelve deaths from hydrophobia in 1838, and four in 1839. Then only one, three, four, two, three, two, in the successive years to 1845, none in 1847, '49, and '52, and only one in 1846, '48, '50, '51, and '53. Seven were returned in 1854, and two in 1855 and '57. None in 1856 and none in 1858, '59, '60, '61, and '62. Two in 1863, and none again in 1864, but nine in 1865, and six in 1866. There were three in 1867 and '69, none in 1868 and '70; one in 1871, '72, and '73. Then there were nine in 1874, six in 1875, six in 1876, and sixteen in 1877; five in 1878, two in 1879, three in 1880, five in 1881, four in 1882, eight in 1883, nine in 1884, and in 1885 no less

* The following statement of the deaths from hydrophobia which occurred in the Punjab is taken from a report by Brigade-Surgeon Bellew:—Population of the province, 17,514,978. Deaths from hydrophobia: in 1879, 69; 1880, 107; 1881, 139; 1882, 128 1883, 117; 1884, 158; 1885, 146.

than twenty-seven. In 1886 the number suddenly fell to nine—after muzzling was enforced—and in 1887 and 1888 there was not a single death. In twenty years (1869–88) there were 780 deaths in England and Wales.

In England, the greatest number of cases of hydrophobia occur in Lancashire, Cheshire, and the West Riding of Yorkshire, and the next greatest number in London and the Home counties.

According to the popular belief, the disease is more frequent in the hot season than during winter and spring. Of 132 cases, throughout England and Wales, fifty-one occurred in July, August, and September.

Rivers sometimes seem to limit the diffusion of hydrophobia in a remarkable manner. Schrader has stated that in 1852 and 1853, when it was raging in Hamburg and in the neighbourhood on both sides of the Elbe, no cases occurred on the islands in that stream.

Only some of those who are bitten by rabid animals are attacked by hydrophobia; several writers agree in fixing the proportion at about 50 per cent., but this is certainly too high. Inasmuch as the disease if left to itself is, so far as is known, always fatal, we may take the mortality among persons bitten by rabid dogs as indicative of the frequency with which the disease is developed. The statistics in the department of the Seine for 1887, reported by M. Dujardin Beaumetz, and those of the county of Lancaster for the same year very nearly agree: in and near Paris there were 7 deaths out of 44 bitten; in Lancashire 6 deaths among 36 bitten, or about 16 per cent. Some of those who escape perhaps owe their immunity to an idiosyncrasy which renders them insusceptible of the virus; at least this appears to be the case in the dog. Sir Thomas Watson mentions that a dog was caused to be bitten repeatedly, but without any result.

Another circumstance affecting the transmission of the disease is the presence of clothes or other coverings, by which the teeth are wiped clean of the virus before they penetrate the skin. The undoubted fact that rabid wolves are more dangerous than dogs may be due to their flying straight at the naked throat. Youatt and all modern writers are agreed that a breach of the cutaneous surface is necessary to allow of the entrance of the poison; in Sir Thomas Watson's oft-quoted case, however, both the coachman and his fellow-servants declared that the terrier dog by which he was inoculated had drawn no blood, but merely indented the skin of the hand: the saliva had (if the observation was accurate) entered the lymph channels by the *rete mucosum*. Mucous membranes may perhaps be capable of infection without any previous lesion. A case is recorded in which a rabid dog licked the face of a sleeping man near his mouth, and communicated the disease, although not the slightest scratch or abrasion could be found after a strict search.

The large experience recently obtained at the Pasteur Institute in Paris has amply confirmed Mr Forster's belief that bites on the face are the most fatal, and probably they have the shortest incubation. Next come the hands, and lastly, the parts habitually covered.

A question of some consequence to pathologists is whether the virus retains its powers after the death of a rabid animal. Mr Youatt thought that this was not the case; but Bollinger cites the case of a student at the Veterinary College at Copenhagen, who opened the body of a dog that had died of the disease the night before; his finger was slightly fissured at the time, and about six weeks afterwards he died of hydrophobia. The poison, however, appears to have little power of resisting decomposition, for no case

appears to be recorded in which it has been transmitted by fomites, or in any other way than directly from the saliva, or (experimentally) from the nervous centres.

Seat.—Until lately it was supposed that hydrophobia, like other neuroses, has no morbid anatomy, at least so far as the nervous centres are concerned. But Benedikt, as early as 1875 ('Virchow's Archiv' for that year, p. 537), and Dr Gowers ('Path. Trans.,' 1877), Dr Coats ('Med.-Chir. Trans.,' 1878), and Dr Ross ('Path. Trans.,' 1879) have found that the vessels in the bulb towards the floor of the fourth ventricle are surrounded by masses of leucocytes within their sheaths, and that collections of these exuded cells, forming miliary abscesses, may occur among the nervous elements. Similar changes, but less marked, were also found in the spinal cord. They do not, however, occur in all cases, for in some beautiful preparations made by Dr Frederick Taylor no deviations from the normal appearances are to be recognised. On the other hand, preparations made from the patient who died in our wards in 1885, by Dr Hale White, showed unmistakable extravasation of leucocytes, and here and there of blood-discs, in the sheaths around the vessels in the bulb. In the spinal cord and in the brain the lesions were more scanty and doubtful.

Experimental evidence confirms the belief that the cord and bulb is the seat of the disease.

Other conditions, more or less constantly found after death, are congestion of the mucous membrane of the pharynx and epiglottis, of the stomach with hæmorrhagic erosion, and of the lungs. They are more uniform in rabbits than in human beings.

Pathology.—Hydrophobia offers some of the most difficult problems in the science of medicine. What becomes of the virus during the prolonged and indefinite stage of incubation? What new process gives rise to the first characteristic symptoms? Some writers suppose that a "recrudescence" takes place, the poison having hitherto been imprisoned in the wound, but being at this time absorbed in the blood. One cannot imagine that hydrophobia is due merely to a transference of morbid action along the nerves (a peripheral ascending *neuritis migrans*, such as perhaps occurs in tetanus), for fresh poison is generated, so that the saliva and even the blood become infective. Indeed, if it is the fact that a dog can communicate the disease during the period of incubation, the whole theory of recrudescence must be given up.

There can, however, be no reasonable doubt since Pasteur's experiments, to be presently described, have been made, that hydrophobia is a specific contagious disease, a "zymotic" "blood-poison." The microbe on which it probably depends has not yet been discovered.

Diagnosis.—Hydrophobia is not generally difficult to recognise. There has been no doubt as to the nature of any of the cases, all of them fatal, that have been observed at Guy's Hospital within the last few years. One of the oddest of all vagaries of medical opinion is the notion that there is really no such disease, and that all the persons who are supposed to have died of hydrophobia have really succumbed either to traumatic tetanus or to fright. This idea seems to have been started early in the century by Bocquillon, and it was upheld by Sir Isaac Pennington, Regius Professor of Physic at Cambridge, and more recently by Prof. Maschka, of Prague. But as Sir Thomas Watson long ago remarked, young children and idiots, who could not have understood anything about the disease, have died of it, and many

of the adults who have been attacked have been men of strong mind who refused to believe that they were seriously ill. As for tetanus, the symptoms in most cases are altogether different.

It must, however, be admitted that medical literature contains a considerable number of well-recorded cases, concerning which it is perhaps impossible to say positively whether they were instances of hydrophobia or not. The difficulty is with regard to those cases in which recovery is supposed to have taken place. For all experience tends to show that whenever the clinical characters of hydrophobia are present in a typical form the patient invariably dies, or, in other words, nearly every case in which the fatal issue has been arrested seems to have presented some feature or other which casts a doubt upon its genuineness. And yet one cannot deny that, taken as a whole, the symptoms have often resembled those of hydrophobia more closely than those of any other known disease.*

In some cases of epilepsy, hysteria, or mania, there is spasmodic difficulty in swallowing liquids which may be more or less like that which occurs in hydrophobia. But the doubt, if any, is soon dispelled by the progress of the disease.

Prophylaxis.—If all rabid animals could be alone destroyed it would be possible to "stamp" out the disease, but this is impossible, for beside domestic dogs we have to account for wolves and other animals.

A more hopeful plan is to prevent dogs from biting by enforcing the use of a properly constructed muzzle. By this means hydrophobia has been banished from Berlin; and its success when used in London has been remarkable. In 1885 twenty-seven persons died of hydrophobia in London, beside twelve in the suburbs. In December of that year dogs were muzzled. In 1886 only nine persons died of the disease, and those persons were bitten before the muzzling order was issued. In December, 1886, the order lapsed, and was not renewed. In 1887 and 1888 there were no deaths from hydrophobia in or around London. Between February and October, 1889, ten deaths have occurred.

Treatment.—The treatment of hydrophobia by drugs is hopeless. Morphia,

* Here, for example, is a case recorded by Dr Nicholls, of Chelmsford, in the 'Lancet' for 1878. The patient, a carter, aged twenty-five, was bitten by a stray dog in a neighbourhood where there had recently been a case of hydrophobia, and where several dogs known to have been bitten were still at large. Some weeks afterwards, having in the meantime thought little about the matter, he became weary, his legs ached, and he had loss of appetite. Two days later he refused a glass of ale at a customer's house, saying he could not drink it. On the fourth day he drank a quantity of coffee, but said that he "gulped it down," and complained at intervals of his throat. He was also much annoyed by trifling noises, and particularly by a toy windmill outside his house. On the fifth day, having delivered a load of coals in the country, he called at a public-house, and after three efforts got down a pint of ale. He then muttered that he was as thirsty as ever, wherefore another cup was passed to him, but on attempting to sip from it he failed. After this he drove into the town, dashed through the streets at a gallop, and became maniacal and unconscious. Dr Nicholls was called to him and found him with a rope tied round his legs, struggling furiously, and beating his arms and head. He was uttering a peculiar noise, between a howl and a scream. His face was livid and covered with a cold sweat; his jaws were clenched; he was foaming at the mouth. Convulsions like those of tetanus then came on and continued at intervals for about twenty-four hours, being, however, controlled to some extent by inhalations of chloroform. The opisthotonos was extreme, the body resting on the head and heels for a minute at a time. On the evening of the sixth day he partially regained consciousness, and asked for drink, which he gulped down in small quantities, the greater portion being expelled from the mouth. Two days later he displayed a remarkable horror of anything white, such as a bandage, a basin, a white glove, &c., turning aside and becoming convulsed as soon as he saw them. By about a week from this time he was well. If the disease was not hydrophobia, what was it?

chloral hydrate, or inhalation of chloroform, relieves the distressing spasms for a time at least, if employed boldly, but do not even postpone the fatal issue. Curare is probably equally useless, and the same must be said of cannabis indica, atropine, cocaine, salol, and methane, as well as of quinine, mercury, and the other drugs employed by Morgan and the older physicians (see Mr Dowdeswell's paper in the 'Proc. Roy. Soc.' for 1887). Darkened rooms, hot baths, electricity, and every other appliance that reason or credulity could suggest have been fully tried with equally negative results.

Promoting free bleeding from the wound, sucking and washing it, and applying nitrate of silver or other suitable caustic,* are rational methods of treatment, and, if adopted early, may undoubtedly prevent the virus from reaching the general circulation, and thus save the patient's life.

The Buisson or sweating treatment, still used in Russia, has been tried and found utterly useless.

Since, however, the first edition of this chapter was written, everyone has heard of the researches of M. Pasteur and of his method of preventing or even curing hydrophobia by inoculation of an attenuated virus. The following is a brief account of these remarkable investigations.

Starting from the belief that hydrophobia in man and rabies in dogs and other animals is a contagious disease, Pasteur ascertained that the fresh cord and bulb of a rabid dog, when pounded up with sterilized broth makes a highly contagious materies morbi; and this, injected under the skin or into the veins, or, most certainly and rapidly of all, under the dura mater, will reproduce the disease in a dog, cat, rabbit, or any other susceptible animal. As above stated, the symptoms vary for different species and even for different individuals; but after death the cord will again furnish the contagium, so that the identity of the disease is proved.

Next he set to work to attenuate the virus, as he had that of anthrax (cf. *supra* p. 358); and devised a plan of drying the cords in a warm, dry, sterilized atmosphere (20° C. is the temperature chosen, or about 68° F.); by this means the virus is rendered less powerful, and becomes progressively weaker day by day. When broth, charged with these dried cords, is introduced into a dog, he undergoes the disease in a mild form, and can then without danger be inoculated with a stronger virus, until at last he is rendered "refractory" to the most recent and intense contagion, or to the effects of direct inoculation from a rabid dog by biting.

The efficacy of this prophylactic or "preventive" treatment (called "vaccination" by M. Pasteur) is not a matter of question. If protected and unprotected dogs or rabbits are bitten by the same rabid dog or cat, the former escape and the latter die.

It would therefore be theoretically possible by inoculating all living dogs to "stamp out" hydrophobia for ever; just as, if vaccination were made compulsory everywhere for a generation or two, smallpox would become extinct and vaccination itself no longer needful. But this is as impracticable for hydrophobia as it is at present hopeless for variola. All that can be done by way of prophylaxis is to diminish the number of dogs by taxation of the owners, to destroy masterless dogs, and to enforce the use of muzzles.

Pasteur next tried whether it is not possible to anticipate the march

* Mr Youatt did not practise excision, but trusted entirely to cauterisation with nitrate of silver. He himself was bitten seven times, and operated on 400 persons besides, among whom he had only one death, which he ascribed to fright.

of the disease, by taking advantage of its undoubtedly long incubation-period and using attenuated virus with a shorter period, so as to overtake the original virus and fortify the organism against it, before its natural effects appear. Trials of this "protective" method on dogs and rabbits already bitten proved encouraging; and at last, when urged to do something to save a child named Joseph Meister, who had been severely bitten by a mad dog, Pasteur, as he tells us, with great anxiety, inoculated him with attenuated virus on July 6th, 1885. The result proved satisfactory; the boy recovered, and many other persons bitten by rabid (or often, in all probability, by non-rabid) dogs applied to Pasteur, and received "protective' inoculation. The numbers increased enormously, patients arriving from all parts of France, from Italy, Russia, England, and even from America and India. A certain number of deaths with undoubted hydrophobic symptoms occurred, particularly among several Russians who had been bitten by rabid wolves. Pasteur's results were not completely confirmed by independent investigators, *e. g.* Professor von Frisch, of Vienna, and he was violently attacked, not only by fanatical opponents of experimental pathology, but by certain French physicians. The difficulties in the way of a sound conclusion are serious. For, first, no one knows how many of the people who have been inoculated had really been bitten by a rabid dog at all. Secondly, when a bite is inflicted on a part covered by clothing, the venomous saliva is generally wiped off, and so the person bitten escapes. Thirdly, many who were bitten had been well treated by caustics, and thus the virus may have been, and no doubt frequently was, destroyed before they were inoculated. Lastly, the proportion of men or animals who, from some "insusceptibility" (*i. e.* some individual unknown cause), escape the disease even when the virus is fairly injected is unknown, though, judging by analogy from syphilis and from vaccinia, probably a small number by comparison.*

The serious question has also to be considered whether the intended protective inoculation may not, if unwittingly employed on persons who have not really been infected before, produce a fatal form of the very disease against which it is supposed to protect.

It cannot be said that these questions are fully answered, or that all the difficulties have been surmounted. But a report, presented to the President of the Local Government Board by a Committee appointed for the purpose of investigating this subject,† goes far to prove to unprejudiced critics that not only has Pasteur discovered an efficient "preventive," *i. e.* strictly prophylactic treatment of hydrophobia—a fact of great scientific importance—but that he has also succeeded in applying the same method to the "protective" or therapeutical treatment of the same dreadful malady when it has already been contracted.

Among a total of 2682 persons inoculated at the Pasteur Institute, forty are said to have died of hydrophobia. Nine of these deaths occurred among forty-eight persons who had been bitten by wolves—a peculiarly dangerous kind of rabies, and met by a more rapid and probably more hazardous process of inoculation.‡

* See M. Roux's "Croonian Lecture before the Royal Society," reported in the 'Brit. Med. Journ.' for 1889, vol. i, p. 1269

† The Committee consisted of Sir James Paget, chairman, Sir Joseph Lister, Sir Henry Roscoe, Professor Burdon Sanderson, Dr Quain, Dr Brunton, and Dr Fleming, with Mr Victor Horsley as secretary.

‡ The ordinary method was to inject on the first day of treatment virus derived from

Excluding these, of 2634 persons bitten (or supposed to be bitten) by mad dogs, only thirty-three died, a percentage under 1·5, and far less than that assigned by any computation to cases treated in other ways or not treated at all.

Of 233 persons bitten by undoubtedly rabid animals (as proved by inoculation from the spinal cord or by rabies appearing in other animals bitten by them) only four died, instead of perhaps fifty and almost certainly twenty.

Of 186 persons bitten on the face (the most dangerous part) by undoubtedly rabid dogs, only one twentieth died, instead of the previously probable proportion of at least a fourth.

Ninety cases were personally investigated by Dr Burdon Sanderson, Dr Brunton, and Mr Horsley, who went to Paris for the purpose. Among them no death had occurred. In thirty-one there was no clear evidence that the dog which had bitten the patient was rabid; but in twenty-four the bite had been inflicted on an uncovered part of the skin by undoubtedly rabid dogs.

Lastly it appears certain that the ordinary inoculation as now practised by M. Pasteur is perfectly safe, although there is room for fear that the *méthode intensive* may be attended with a certain risk.

Whether the protection will last a lifetime, or longer than the two years or more which have now elapsed since it began to be practised, cannot of course be at present known. It is possible that further experience may modify the conclusion above stated; but no dispassionate critic can withhold his admiration from the insight and ingenuity, the zeal and perseverance, which M. Pasteur has displayed, or can doubt that humanity is indebted to him for what, on the lowest estimate, is a more than promising method of treating a frightful and otherwise hopeless disease.

a cord dried for fourteen days; on the second, that of a cord dried for thirteen days; on the third, that of a cord dried twelve days; on the fourth, that of an eleven days' cord; fifth, ten days; sixth, nine; seventh, eight; eighth, seven; ninth, six; and tenth, five days. These injections were afterwards made more frequent, and the increase of strength more rapid. But for very severe cases, like those of wolf-bites, Pasteur now uses a *méthode intensive*, injecting on the first day of treatment virus derived from cords dried for fourteen and thirteen days; on the second, for twelve and eleven; on the third, for eleven and ten; on the fourth, ten days twice; on the fifth, nine days twice; on the sixth, nine days again; on the seventh, eighth, and ninth, eight days; on the tenth, eleventh, and twelfth, seven days; on the thirteenth and fourteenth, six days; and on the fifteenth and last day of treatment virus of maximum intensity derived from a cord of only five days' drying.

DISEASES OF THE NERVOUS SYSTEM

Local or regional diseases compared with general and specific diseases—Principle of their classification and nomenclature—Order to be followed in this work. Nervous Diseases—Peculiarities of this group—Arrangement adopted.

THE group of specific fevers of which we have now concluded the survey is the only one which can be called "natural." They agree in ætiology, and in the nature of the disturbance set up by the exciting cause, *i. e.* in their pathology; they agree in being infectious; in their general symptoms and course, and particularly in their relations to time; in their protective power; and, lastly, they are usefully studied together from the practical points of view of diagnosis, prognosis, and treatment.

Even in this group, however, we have seen that some members are more closely related than others—the eruptive fevers, for instance; and some have been put together from such accidental characters as their being derived from the lower animals, or being confined to tropical climates. Moreover, as in all natural classifications, certain members of the group, as Tuberculosis, Ague, Actinomycosis, are wanting in some of its characters, and might, not without reason, have been excluded, while other specific febrile diseases have been postponed to later chapters, as Mumps and Whooping-cough, for practical convenience, or, as Rheumatic Fever, in order to group it with other diseases, different in pathology, but closely connected clinically. Lastly, some general diseases are in important respects local—witness Enterica and Diphtheria—while others, counted among local disorders, undoubtedly affect the whole organism, as Gout and Purpura, Leprosy and Pneumonia.

It is desirable to dwell on these considerations in order that the student may clearly understand the futility of attempts at a scientific nosology. Diseases are not natural objects. They are structural or functional disturbances, viewed from the human standpoint of life and death, comfort and pain. They are dissimilar in origin and nature, and therefore incapable of uniform classification. It follows that no one system of Nosology can produce a useful, a scientific, or even a symmetrical result.

If we classify diseases by their *origin* we can form certain large classes which would express true relations, but would be impracticable for adoption in a systematic treatise. For instance, we should collect together—*parasitic* and *contagious* disorders; *malarial* diseases; those directly the result of mechanical *injury*, of chemical irritants, or of heat—"traumatic" as they are sometimes called; those produced by exposure to *chills*, the "catarrhal," or, as some German writers unfortunately call them, "rheumatic" diseases; those produced by chemical *poisons* ingested, as lead colic, lead palsy, and saturnine gout, the "zinc-ague" of brassfounders, mercurial tremors and stomatitis; those produced by *drugs*, as urticaria from copaiba;

those produced by unwholesome *food*, as alcoholic delirium and cirrhosis, gout, and the long list of dietetic disorders.

Then would come the diseases of imperfect *development*, in intra-uterine life or in infancy, at dentition or at puberty, and the large and important series of morbid changes which are the result of premature or normally supervening *senile* changes—atheroma, fatty and fibrous degeneration, involution of the uterus or the ovaries or the breast; atrophy of certain organs and hypertrophy of others. These, when delayed to the full term, are the "natural" diseases which lead to a kindly death.

If we attempted a *pathological* classification we should place next to the specific fevers those maladies in which the same process of pyrexia is excited by local inflammation, and make a class of inflammatory fevers, as was done by Cullen and by Hildenbrand.

A nosology based on *morbid anatomy* would follow the lines traced by Rokitansky and his successors, but we have only to turn to the best systematic works on the subject to see how unsuitable such a plan would be for a treatise of medicine. Of many diseases we know neither the seat nor the cause; some whose cause we know have no anatomy, and many anatomical changes have no clinical history.

A *histological* classification would be impracticable as the basis of a complete system; although it is instructive to remember that serous membranes, lymphatic organs, mucous surfaces, bones, and secreting glands have points in common under morbid as well as under healthy conditions. We shall, indeed, find it convenient to group together primary diseases of the blood, diseases of the skin, and diseases of the joints.

The only remaining course open to one who plans a systematic treatise like the present is, after setting aside general specific diseases, to put those together which affect the several organs—the brain and spinal cord, the larynx and lungs, the heart, the digestive apparatus, and so on; and this plan is followed here, as it has been by Dr Bristowe and by other recent writers. Functional diseases are classed with those of the structures which subserve the disordered functions—neuralgia with neuritis, epilepsy with cerebral diseases, asthma with bronchitis. Diseases of uncertain seat are arranged according to their most important symptom, or according to custom and convenience. Thus, exophthalmic goitre goes with disorders of the circulation, and diabetes with those of the urine; for we have no satisfactory grounds for putting them anywhere else, and at least readers know where to find them.

Nomenclature.—Closely allied to classification is terminology. In the case of specific diseases with a constant origin and a definite course, the best names are those which, first, are meaningless; secondly, consist of a single word, and that short, distinctive, and euphonious; and, thirdly, can form adjectives. Syphilis and Typhus (not typhus fever) are two of the best names we have. When, however, the disease is less definite and certain, names otherwise good become ambiguous, as Erysipelas, Diphtheria, and Pneumonia.

In choosing names we must in the end be guided by usage—

Quem penes arbitrium est et jus et norma loquendi;

but we should follow the best usage; and in this country it is in every way desirable to keep, as nearly as may be, to the official nomenclature of the Royal College of Physicians and the Registrar-General.

Some names are vernacular, like Measles, Mumps, Smallpox, Shingles, Dengue, Glanders, Ague, Gout, and these are excellent

Others are Greek or Latin names, classical or barbarous, as Morbilli, Variola, Zona, Psoriasis, Lupus, Scabies, and these are as good or better. Similar names may be more or less successfully coined, as Diphtheria, Pertussis, Enterica, Equinia, Purpura, Leuchæmia.

Personal names are undesirable. They are seldom generally accepted; they are cumbersome, they are often ambiguous, and they are seldom historically accurate. Such are Pott's disease, Morbus Maculosus Werlhofii, Bell's palsy, Maladie de Raynaud, Graves' or Basedow's disease, Cruveilhier's paralysis, Parkinson's disease, Hodgkin's disease, Maladie de Charcot.

When the anatomical lesion which causes the symptoms is known, it furnishes the best designation of the whole train of structural and functional disturbance, as abscess of the liver, annular cylindrical carcinoma of the descending colon, lithic-acid renal calculus, cirrhosis of the liver, stenosis of the mitral valve, glioma of the middle lobe of the cerebellum, and so on. These, however, are rather diagnoses than names.

Better, perhaps, are the names which express the pathological processes which lead to the structural results, *e. g.* suppurative hepatitis, anterior polio-myelitis, tubercular peritonitis, acute yellow atrophy of the liver.

Often, when neither the structural change nor the morbid process is certainly known, we must be content with clinical names, denoting a recurrent group of physiological events—a "complex of symptoms" the German writers call it—as Epilepsy, Chorea, Asthma, Chlorosis, Scurvy. Many such terms—Dropsy, Jaundice, Hemiplegia—have now become symptoms rather than "diseases," steps to a further diagnosis. But often no further step is at present possible; the symptom is the disease (see p. 4).

The order in which we take the various local diseases is of little consequence. We shall here follow the traditional order of taking the most noble cavity, the Head, first; after the diseases of the brain and nervous system, will follow chapters on the diseases of the Chest; then will come diseases of the Abdomen and Digestive organs generally, of the Liver, the Kidneys, and the Spleen, with its lymphatic allies; then diseases of the Bones and Joints, diseases of the Blood, and, lastly, those of the Skin.

In entering upon the study of Nervous Diseases we begin the most difficult department of medicine. Unlike the lungs and heart, the brain works silently, so that no auscultatory phenomena accompany its disorders. From the abdominal viscera it differs in being beyond the reach of palpation and percussion, and in yielding no secretions for chemical examination. Hence *the symptoms of nervous disease are, almost without exception, those of perverted nervous function.*

We cannot absolutely separate the diseases of the nervous system into those which affect respectively the brain, the spinal cord, and the nerves; for the precise seat of many of these disorders is still obscure or doubtful; and there are affections which, although they begin in one of these great divisions of the nervous apparatus, afterwards involve the rest. Still, the arrangement adopted here will, as far as possible, be to take first the diseases of the Peripheral Nerves, next those of the Spinal Cord, then those of the Cerebral Centres, and lastly the functional disorders, which are conveniently grouped together as *Neuroses.*

AFFECTIONS OF THE NERVE-TRUNKS

> But pain is perfect misery, the worst
> Of evils, and, excessive, overturns
> All patience. MILTON.

NEURALGIA.—*Definition—Pathology and general characters—Trifacial neuralgia—Neuralgia of arm and trunk—Sciatica—Treatment of neuralgia.*

PERIPHERAL PARALYSIS.—*Causes—Motor palsies of vertebral nerves in particular—The reaction of degeneration—Sensory paralysis—Pain—Causalgia—Glossy skin and other trophic results—Diagnosis, prognosis, treatment—Paralysis of cranial nerves—Motor, of the portio dura, hypoglossal, and oculo-motor—Sensory, of the trifacial and olfactory—Treatment.*

PERIPHERAL NEURITIS.—*Its history and symptoms—Histology—Causes—Prognosis and treatment.*

THE affections of the nerve-trunks may be broadly divided into two clinical groups. In one *pain* is the principal symptom; these affections constitute the *Neuralgiæ*. In the other group the chief symptoms are *loss of muscular power and of cutaneous sensibility;* these are commonly called the *Peripheral Paralyses*, to distinguish them from similar conditions due to diseases of the brain or spinal cord.

NEURALGIA.—In the former of these two groups the principal, and sometimes the only symptom is *pain*. Pain, however, is a symptom common to many, indeed to most, diseases, and since it is a function of the nervous system, all pains are in one sense neuralgia.

Now, pain itself, although it is so familiar to everyone, seems nevertheless, to be an ultimate fact of sensation, incapable of definition or of explanation. It is not enough to say with Erb, that pain is "the reaction of the sensorium to a certain degree of excitation beyond that which would cause common sensation," for hyperæsthesia may exist without pain, and pain is often accompanied by anæsthesia. So different, indeed, are the two conditions of the sensory apparatus that some physiologists have been driven to the supposition that there are afferent nerves and centres for painful impressions, distinct from those for common sensation and for temperature.

Physiologically, pain may be excited by injury to one of the sensitive nerves in its course or at its periphery, or possibly by injury to its centre. The pain is in either case referred by consciousness to the peripheral distribution of the nerve. The most common cause of pain is increased pressure on the nerves, but mechanical injury, and chemical or electrical disturbance, may produce the same effect. Pressure on the papillæ and their touch-corpuscles or other tactile end-orders produces the sense of touch; when these are destroyed, as on the surface of an ulcer, no true sensation of touch is produced: but pain may still be excited. If, however, the pressure or injury passes a certain limit, pain disappears again and numbness or paralysis ensues.

Under ordinary circumstances, the impressions which give rise to pain are made upon the *terminal* filaments of a nerve; and the sufferer recognises as the seat of the pain the part to which the filaments in question are distributed. In neuralgia, on the other hand, the pain is said not to be excited by direct irritation of the distal extremities of the nerve to which it is referred.

If we accept this distinction, we must deny the pains of toothache when directly referred to the aching tooth to be true neuralgia, and we must admit as true neuralgia the pain produced by an aneurysm or other tumour pressing on the branches of nerves.

Practically, however, our knowledge of the special physiology of pain is not enough for us to be sure that the above distinction is valid in all cases, still less to apply it. We must therefore be content to call neuralgia that kind of pain which is so far as we know primary or idiopathic. When pain is not produced by pressure due to inflammatory engorgement of vessels (the most frequent cause), when it is not caused by injury or other direct cause, then we may call it neuralgia, at least provisionally. This is like the way in which we shall find that epilepsy and some other functional disorders of the nervous system are defined. Its justification lies in the empirical fact that the pains which on this diagnosis are called "neuralgia," have certain clinical characters in common which separate them from secondary pains. Before enumerating them, however, it should be mentioned that in two groups of cases we can give some explanation of neuralgia, which puts it on a separate pathological basis. In one, the neuralgia is really due to peripheral irritation, but this is not applied to the painful nerve, so that the patient is mistaken in his interpretation of the local sign. This is sometimes called "reflex neuralgia." A good instance is the trifacial neuralgia which is often excited by disease of a tooth. Such an affection is most readily explained by supposing that the irritation is directly transferred from one nerve-nucleus to another within the cerebro-spinal centres. In the other form of neuralgia, of which Sciatica may be taken as an example, there is some reason to believe that the morbid process begins in the trunk of the affected nerve, and that it is a form of local "neuritis" or perineuritis. If we were sure of this, it would be well to exclude sciatica from the category of neuralgia, and to class it with other inflammations of the peripheral nerves: the functional disorder would be recognised as organic, and the "disease" which was a symptom would become a local inflammation (cf. p. 4).

The clinical characters of neuralgia are as follows:

(1) The pain, instead of being only referred to the peripheral extremities of the nerves, is felt to shoot or dart along their course.

(2) The pain comes and goes; it rises rapidly to severe intensity and as rapidly subsides again.

(3) The pain is stabbing or piercing in character; not throbbing like that of inflammation, nor grinding like that of toothache, nor increased with movement like that of lumbago. It has not the disabling, ineffectual, baffled character of the pain which accompanies stricture, dyspnœa, or the efforts of defæcation or of childbirth, nor the sickening, paralysing pain of orchitis; but it is clear, sharp, and thin, high-pitched in quality, coming in bouts which force tears or cries from the sufferer, and leave behind them a massive, wearying after-swell of exhaustion.

(4) Certain "tender points" are developed, pressure upon which causes

increase of the patient's sufferings, while they are often, though not always, the seat of spontaneous shooting pains. It was Valleix who first drew attention to these *points douloureux*, as he termed them; and he maintained that they are of great importance in the diagnosis of neuralgia. He further showed that they are constant in position for each of the principal cutaneous nerves, corresponding generally with the spots at which they emerge from bony canals or from fasciæ. Trousseau afterwards laid stress upon the presence of an additional tender point at the spinous process of the vertebra, beneath which the affected nerve escapes from the spinal canal; this he terms the apophysial point. With regard to the frequency of the occurrence of "tender points" in cases of neuralgia there has been much diversity of opinion, dependent perhaps on the varied scope of the term neuralgia as used by different writers. Thus Eulenburg, who includes migraine, found tender points in only about half the cases which he examined. Anstie insisted on the fact that it is only when the pain reaches a certain degree of severity and of persistence that they develop themselves. It seems probable that they are, after all, merely spots at which nervous filaments happen to be so placed that they can be readily compressed. In cases of sciatica the external popliteal nerve is much more sensitive to pressure on the affected than on the healthy side, in that part of its course in which one can without difficulty feel it—namely, when it is running under cover of the biceps tendon.

(5) Another character of neuralgia, which is remarkably constant, and is often useful for diagnosis, is its limitation to the nerves of one half of the body. Even when it attacks a large number of nerve-trunks on the same side it seldom extends across to those of the opposite side; and it is never absolutely symmetrical, presenting the same degree of severity, and reaching the same extent of distribution, both to the right and to the left of the spinal column.

(6) A sixth characteristic of neuralgia is, that after its subsidence it leaves the affected parts tender to the touch.

Even with the help of these characters, it is often a question whether a given pain should be rightly termed neuralgia or not. The pain in the shoulder which attends abscess of the liver, the pain in the arm which is experienced in aortic aneurysm, the pain in the testicle which is caused by a renal calculus, are each typically neuralgic, because they are not due to lesions of the shoulder, the arm, or the testis; and so also are gastrodynia and angina pectoris, when they are not due directly to irritation of the terminal filaments of the gastric or the cardiac nerves. Even the pain in the side which accompanies hepatitis or pleurisy is in part neuralgic, for it often extends along the cutaneous branches of the affected nerves far beyond the area of inflammation, and the skin itself may be tender.

But it is doubtful whether the pain, "neuralgic" as it is in character, which accompanies the passage of a renal calculus should be described as neuralgia; and *migraine*, which was regarded as a form of neuralgia by all the older writers, and even by Eulenburg and Anstie, will be described in this volume, according to modern practice, as a separate neurosis. It is, indeed, certain, for reasons that will be given hereafter, that the seat of migraine is in the nervous centres themselves; but it is equally certain that the pain is referred to the cutaneous nerves of the scalp, and shoots and darts along in the course of their fibres. Moreover, in persons who have suffered from this disease for some time, true "tender points" are developed, exactly as in an ordinary neu-

ralgia; and other trophic changes occur, which show that a morbid influence has been reflected outwards upon the hair and other superficial tissues. Thus it does not appear easy to exclude migraine from the definition of neuralgia, while the common "reflex" forms are allowed to retain their places. Perhaps the difficulty may be removed by the consideration that the nerves of the scalp may fairly be supposed to bear the same relation to the brain beneath, which has been shown by Hilton and by van der Kolk to exist between the superficial nerves generally and the organs which lie beneath.* Just as almost any disease of the lung may be accompanied by pains referred to the nerves which are distributed to the skin over the chest, so we shall find that various affections of the brain and its membranes may be attended with pains running in the course of the frontal, the temporal, and the occipital nerves. The pains themselves are "neuralgic," but the presence of other symptoms show that the disease, as a whole, is something more than neuralgia.

However this may be, it is certain that neuralgia bears a close ætiological relation to the neuroses in general, as we shall find in studying the different local varieties of the disease.

Neuralgia of fifth nerve. Trifacial neuralgia. Prosopalgia. Tic douloureux. —Most cases in which pain is referred to the branches of the first division of the fifth nerve belong to Migraine; but there remain numerous instances in which the lower or middle branches, or all three at once, are affected; and among them is included the most severe of all neuralgiæ—a terrible malady, for which the most convenient name is, perhaps, *tic douloureux*. By Trousseau it is called "epileptiform neuralgia," apparently because it occurs in paroxysms with sudden onset, which so far resemble the attacks of epilepsy. It was described by Fothergill, in 1773, as "a painful affection of the face, distinct from the rheumatism and the ague in the face." True tic douloureux is happily very rare.

The absolute suddenness with which the pain of tic douloureux comes on is one of its most remarkable characters. The patient is perhaps sitting quietly reading, when he jumps up from his seat, and rushes up and down the room, with his hand forcibly pressed against his cheek; or he rocks himself backwards and forwards in the chair, crying out or uttering deep groans. In ten or twenty seconds, or a minute at the longest, the paroxysm is over. It ceases as abruptly as it began. The pain sometimes affects all the branches of the fifth nerve; sometimes only those of the second or of the third division. In certain cases, the muscles of the side of the face are thrown into violent spasms during the fit of pain, so that the patient makes horrible grimaces and contortions. Flushing of the face and eyes with lacrymation, usually following decided pallor, is very frequently present, and shows that vaso-motor and secretory fibres accompany the fifth nerve. The paroxysms may return every few minutes. Trousseau mentions one patient who had sometimes twenty in an hour; in the worse cases they do not intermit, even during the night. They are often brought on by movements of the jaws as in speaking, or in eating or drinking; and sometimes

* This remarkable "sympathy" between the viscera of the great cavities and the nerves (vaso-motor as well as sensory) of corresponding parts of the surface is probably referable to the fact that the visceral and parietal nerves were once united, before the splitting of the somatopleure and splanchnopleure, and are still connected, at their proximal point of union, with the centres of the several segments of the trunk.

pressure upon one of the teeth will instantly excite an attack. It is not worse at night, and is irregular in the time of its attacks. Sometimes remissions occur, the patient remaining free from the disease for several days together, or even for months. But sooner or later it returns, and is as severe as ever.

The "tender points" are well marked when tic douloureux has lasted for long; they are situated at some or all of the numerous spots at which branches of the fifth nerve emerge from bony channels, or perforate fasciæ. Pressure upon any of them is instantaneously followed by agonising pain, and a breath of cold air upon the face may have a similar effect.

As a result of the disease, when it is of long standing, the whiskers or beard disappear from the affected side of the face, the hair being worn off by friction. According to Trousseau, even the configuration of the bones may become altered, the malar eminence and the prominent part of the lower jaw being flattened down. Herpes zoster has been observed as the consequence of neuralgia, particularly when it affects the infra-orbital nerve. The hair of the scalp in supra-orbital neuralgia and of the beard in infra-orbital is sometimes turned white in the region and on the side of the affected nerve.

A patient who labours under tic douloureux acquires an expression of intense distress and suffering; his countenance is worn and wrinkled, and looks like that of a much older person. But, as Fothergill found, the disease scarcely ever occurs under forty, and often begins at a much later age. Anstie says that the worst case he ever saw was in a woman who was eighty years old when she was first attacked. According to this writer, a special feature in the ætiology of this form of neuralgia is that the sufferers from it almost invariably come of a stock which is tainted with insanity; indeed, they are themselves often the subjects of a suicidal melancholia, and their mental condition is almost always one of moody depression. This is no doubt partly caused by the severe pain which they have to endure, and partly by their inability to eat solid food; moreover, they are very apt to seek a temporary relief in drink, which brings its penalty in increased despondency afterwards.

Sir Thomas Watson gives an account of an autopsy which was made in the case of Dr Pemberton, a London physician of great repute in his day, whose career was ruined by this terrible disease. The os frontis was unusually thick, and a bony mass lay within the falx cerebri. It was supposed that these changes had set up an irritation which caused the neuralgia, but there is no evidence that any branch of the fifth nerve was involved in them, and outgrowths of bone of a precisely similar kind are often found in those who have had no pain in the head or face, nor any cerebral symptoms. Even in a celebrated case related by Romberg, in which the carotid artery was dilated to twice its usual size where it passed through the cavernous sinus, it seems very doubtful whether the so-called aneurysmal condition of the vessel had anything to do with the tic douloureux from which the patient had suffered on the corresponding side of the face; for that disease had existed for eighteen years at the time of his death, and one cannot suppose that the artery had been dilated during the whole of that time. The author has repeatedly seen a similar affection of the carotid at the same spot in the bodies of those who had made no complaint of neuralgic pain during life. Again, it is difficult to believe that the fifth nerve could have been pressed upon, without the sixth and the third

nerves having been first paralysed. Moreover, Romberg found other changes in the affected parts, the nature of which one cannot determine from his account of them, namely, a hard yellow nodule in the crus cerebri, and a softened state, with reddening, of the roots of the fifth nerve.

It does not appear that this form of neuralgia is ever of "reflex" origin or caused by peripheral irritation of any branch of the fifth or of other nerves. There is, indeed, Mr Jeffries' oft-quoted case, in which a triangular piece of china from a broken cup remained lodged in the cheek of a girl and gave rise for fourteen years to violent pains, which ceased a few weeks after its removal by excision; but that patient was too young to have suffered from true tic douloureux. Mr Tomes says that this complaint is never, so far as he knows, caused by irritation from diseased teeth; he quotes, as a warning, a case of Trousseau's, in which the pain came on when the patient touched with the tip of his finger his few remaining teeth, but in which they were extracted without the slightest benefit resulting. Patients, who have in vain had a large number of teeth removed, come to us with their disease unmitigated.

There is a less intense but much more common form of trifacial neuralgia, to which even young persons are liable, and which is often dependent on morbid conditions of the teeth. The pain shoots and darts along the branches of the fifth nerve, but it is generally accompanied with a dull aching or gnawing sensation. It is often distinctly paroxysmal, and (like all other forms of neuralgia) it is especially apt to come on when the patient is over-fatigued or exhausted from want of food. It is seldom severe enough to prevent him from attending to the duties or pleasures of life, although it may cause him great discomfort. In many cases it subsides at once if a glass of wine be taken, or a dose of quinine. According to Mr Tomes, the most frequent cause of this form of neuralgia is chronic inflammation of a tooth-pulp. But other conditions, which are mentioned by this writer and by Mr Salter as being capable of giving rise to it, are the difficult eruption of a wisdom-tooth (or its impaction in its socket), the presence of secondary dentine in a pulp cavity, exostosis, hypertrophy of the crusta petrosa, alveolar periostitis, decomposition of a dead pulp in a confined space, and even the exposure of sensitive dentine, or the crowding of the teeth together from insufficiency of room. In many instances the affected tooth is tender, so that sudden pressure on it, or the contact of substances much hotter or colder than itself, greatly augments the pain. Mr Salter has related one instance in which, although the offending teeth were painful when touched, doubt for a time prevailed as to the real cause of the neuralgia from which the patient suffered, because this returned again and again, there being only a temporary interval of ease after each tooth in succession had been extracted, until the last two were removed at one operation; when the pain entirely ceased. All the teeth had nodules of exostosis on their fangs. It might be expected that any affection of a tooth in the lower jaw would give rise to neuralgia in the course of the branches of the third division of the fifth nerve, and that a diseased tooth in the upper jaw would set up pain in the distribution of the second division. But this is not always the case. Indeed, Mr Salter mentions, as very frequent seats of "dental neuralgia," the supra-orbital nerve, the globe of the eye, the temple, and particularly a spot a little to one side of the vertex. The practical rule would seem to be that the only way of avoiding the risk of overlooking affections of the teeth as causes of

the milder forms of trifacial neuralgia, is to have the jaws thoroughly examined by the dentist in every case. Mr Salter has recorded some curious instances in which the nutrition of parts affected with reflex neuralgia from caries of the teeth, underwent perversion; in one, the iris of the affected eye, from being of a deep hazel colour, became of a dull grey.

The late Dr Anstie believed ('Lancet,' 1866) that in certain cases he traced neuralgia of the fifth nerve to the "reflex" disturbance caused by injuries to distant nerves; once to a knife-wound, by which the occipital nerve was divided, and twice to sickle-wounds of the wrist involving the ulnar nerve. In each instance the pain first came on when the injury was already repaired, and when the cicatrix had become firm.

It must also be borne in mind that pains undistinguishable from those of neuralgia often constitute the earliest symptom of various diseases and tumours of the maxillary and other facial bones, and that such cases may come under the observation of the physician at a time when there is no obvious deformity or swelling to lead the patient to seek surgical advice. There is, in the museum of Guy's Hospital, a specimen of Bright's, in which a morbid growth made its way from the sphenoidal sinuses into the middle fossa of the base of the skull, and doubtless pressed upon the fifth nerve; the patient, a woman of forty, whose countenance showed strong indications of suffering, had complained of an extremely severe pain on the corresponding side of the face, which became more violent in paroxysms.

Neuralgia affecting the neck, arm, and trunk.—Cervico-occipital neuralgia needs but brief consideration. Among the ascending branches of the cervical plexus, the great occipital, or posterior division of the second spinal nerve, is the one to which neuralgic pain is most often referred. Such cases are often due to the direct action of cold. Anstie speaks of a patient who was several times attacked after sitting in a draught which blew strongly on the back of the neck. One must be careful not to overlook disease of the cervical vertebræ.

Cervico-brachial neuralgia generally affects several of the branches of the brachial plexus. Numerous "tender points" are developed, most of them at spots where the nerves pierce the fascia, but some (as, for instance, the inferior angle of the scapula) where their occurrence is not so readily explicable. Glossy skin and causalgia are sometimes present, particularly in cases of traumatic origin. One special feature of this affection is its liability to be aggravated by muscular movements of the arm. Anstie alludes to a case in which, at a time when convalescence seemed to be almost established, the act of playing on the piano for half an hour at once brought the pains back. Salter ('Guy's Hosp. Rep.,' 1867) has shown that neuralgia affecting the nerves of the upper limb is sometimes due to diseases of the teeth. He says that pains in the shoulder and acromion, over the insertion of the deltoid, or at the bend of the elbow, not infrequently depend on this cause; and he cites the case of a lady who, whenever any of the teeth in the left side of the lower jaw became tender from caries, was immediately attacked with severe neuralgia at a circumscribed spot in the forearm.

Among the rarer causes of pains in the arms that might be mistaken for neuralgia may be mentioned disease of the articular processes of the cervical vertebræ. In 1876 a woman was admitted into Guy's Hospital under Dr Wilks, who had for four months been suffering from pains in the right shoulder, round the side, and down the arm to the tips of the fingers. No

cause for her complaints could be discovered, but after a few weeks she was attacked with pneumonia, and died of that disease. Dr Goodhart made a *post-mortem* examination, and found that there was a quantity of inflammatory exudation outside the notch between the seventh cervical and the first dorsal vertebræ. This had its origin in disease of the joint between these two vertebræ; the lowest root of the brachial plexus was involved.

Eruptions of zona and other cutaneous lesions are sometimes observed, but, as with supra-orbital neuralgia, it is often difficult to determine which is the cause and which the effect.

The neuralgiæ of the *dorsal* and *lumbar nerves* need not be described in detail. They are less frequent than those of the face or limbs, and agree closely with cervical neuralgia. The affection described by Sir Astley Cooper as irritable testis is probably neuralgia of the spermatic plexus.

Sciatica.—One of the most important of all the varieties of neuralgia is that which attacks the great sciatic branch of the sacral plexus, and has long been known by the special name of Sciatica (*passio ischiadica*). The part of the nerve which most commonly suffers is that which lies behind the upper half of the femur, but sometimes it includes the whole length of the main branches, and occasionally may be limited to the back of the knee, or to the terminal twigs in the calf or the foot. Its characters differ widely from those of tic douloureux. Instead of paroxysms of acute pain, darting like lightning through the nerve, and separated by intervals of comparative freedom, there is a constant, heavy, gnawing sensation; its intensity is not uniform, but the variations are comparatively slight and uncertain; and if it runs along the affected nerve at all, it travels slowly. It often appears to be worse at night, but this is ascribed by the late Dr Henry Lawson (who was himself a sufferer from sciatica) to the fact that the patient then has less to distract his thoughts than in the daytime. Few diseases induce more peevishness, restlessness, and misery, spoiling the appetite, perverting sleep, and interfering with every kind of work, as well as with most amusements and all athletic sports.

In advanced and severe cases the pain sometimes radiates into the sciatic nerve of the opposite side, or to branches of the lumbar plexus, or to nerves which are still more remote.

The pain is often greatly increased by pressure on the sacral plexus within the pelvis, or at its exit from the sciatic notch, and thus defæcation may be attended with much suffering. The patient is afraid to sneeze or cough, and is very susceptible to a draught of cold air.

When sciatica has lasted for any length of time several "tender points" are generally to be found; one is said to be situated where the nerve emerges from the pelvis, others where its branches pierce the fascia lata, and others over the sacrum, the crista ilii, &c. The whole length of the nerve also becomes unduly sensitive to pressure, and especially that part of the external popliteal nerve which lies under cover of the biceps tendon.

Wasting of the muscles is another symptom of all cases of sciatica which have lasted long. The buttock becomes flattened and flabby, the muscles of the thigh and calf are reduced in size, and feel soft and flaccid. In one case Anstie found the faradic excitability of the gastrocnemius much diminished; so that perhaps the loss of power does not merely depend upon disuse of the muscles. Even within the first few days the patient often

begins to limp in walking, so that he puts only his toes to the ground, and is glad to make use of a stick. Afterwards he lies on the sofa all day long, with every joint of the limb bent, dreading to make the slightest movement. At last the hip- and knee-joints may become rigidly flexed, so that any attempt to straighten them causes severe pain. Painful cramps in the flexor muscles of the toes may come on, especially when the patient is just falling off to sleep. Sometimes fibrillary tremors are observed, or even shaking movements of the limb.

A certain degree of anæsthesia or impairment of tactile sensibility appears to be of constant occurrence in the more severe cases of sciatica, and subjective sensations of numbness and tingling are often present. The affected limb is sometimes paler, and commonly colder than the opposite one; the patient occasionally complains of its feeling chilly, and it is said that the difference of temperature may be detected by surface thermometers.

It will be seen from this account that sciatica differs in the character of the pain and in other clinical features from those given on p. 384, which particularly apply to tic douloureux. Hence there is some doubt as to its being a true neuralgia, and some writers have regarded it not as a single malady, but as a group of affections due in different cases to widely different causes. Thus Sir Thomas Watson spoke of it as being sometimes inflammatory, sometimes "rheumatic," sometimes the result of irritation within the pelvis, or connected with a disordered state of the kidney, and, lastly, as sometimes purely neuralgic.

To some extent this is a question of terms: if we mean by Sciatica to denote any painful affection in the course of the sciatic nerve, we must admit that its pathology is very varied. But if we confine the term to idiopathic neuralgia, it is most important that we should not confound the true disease with the effects of pressure upon the sacral plexus and sciatic nerve from organic disease of whatever kind. In the 'Guy's Hospital Reports' (vol. x, 1864) a case was published that was regarded as an example of sciatica until the patient unexpectedly died; when a large aneurysm was found upon an abnormal artery, which passed down through the sciatic notch and along the back of the thigh. That case is, probably, unique, such a course of the vessel (which is normal in birds) being one of the rarest of abnormalities in the human subject; but a precisely similar pain might be caused by an aneurysm upon one of the regular arteries, or by a bony or sarcomatous outgrowth from the sacrum or os innominatum, pressing upon the nerve. After all, such affections are extremely rare.

More common are supposed to be cases of sciatica due to pressure of impacted scybala upon the nerve of the left side; and the result of emptying the sigmoid flexure is said to prove the fact. But in such cases, as in those which occasionally are met with from pressure during labour or from retroverted uterus or ovarian tumours which have fallen into the pelvis, the pain is accompanied with more decided numbness and paralytic symptoms than attend ordinary sciatica.

As Anstie maintained, the relation of sciatica to rheumatism is altogether imaginary, if any definite meaning be attached to the word "rheumatism;" but there is a kind of sciatica which accompanies lumbago, and probably owns the same cause. Moreover, apart from myalgia or "muscular rheumatism," there is no doubt that occasionally sciatica is due

to gout—probably to local gouty neuritis. We had a marked case of this kind in Philip Ward in February, 1887; a man of thirty-seven, who had suffered repeatedly from hereditary gouty arthritis in the foot, was the subject of severe sciatica of the left side. He had been treated in various other ways without any benefit, and was so quickly and effectually relieved after taking colchicum that one could scarcely doubt the justice of the diagnosis.

Again, some cases of sciatica occurring in syphilitic patients and becoming worse at night, are speedily relieved by iodide of potassium. Here, as in cases due to gout, the pain probably depends upon neuritis of the sciatic nerve; and if so, these and similar cases should be referred to Peripheral Neuritis rather than to idiopathic functional neuralgia.

Nevertheless, Dr Fagge believed that the majority of cases of sciatica are truly neuralgia, and that the points which distinguish it from other forms of neuralgia are not really essential, but in great part attributable to the large size and the superficial course of the affected nerve, and to the way in which it is exposed to irritation and to pressure. The first case of sciatica that he saw in private practice occurred in a gentleman who afterwards came to him for neuralgia of the brachial plexus; and Anstie records three or four cases of a tendency to neurotic diseases in relatives, or of other forms of neuralgia in the patients themselves.

Other writers, however, deny that inheritance or predisposition plays any important part in the ætiology of sciatica, and there is no doubt that it is far more commonly traceable than are other neuralgic affections to accidental circumstances, especially to the action of cold. Lawson states that nine tenths of all cases of sciatica are referable to this cause, and Erb affirms almost as much; exposure to a draught of air when the body is heated, wetting of the clothes, sleeping on damp ground or against a damp wall, have so frequently been followed by sciatica that no doubt can be entertained of their power to excite the disease.

Another frequent antecedent appears to be over-exertion of the lower limbs. In Lawson's own case the complaint came on after a long walk; and sciatica is said to be common in those who work at a sewing-machine.

The fact that certain classes of persons are exposed more than others to the exciting causes of sciatica probably explains the fact that it is more common in *men* than in women (according to Erb, in the proportion of four to one), and that adults from twenty to forty years old are most subject to it. Lawson saw one well-marked case in a boy aged fourteen, who was addicted to masturbation.

The *diagnosis* of sciatica is seldom difficult to the practitioner who first searches for the numerous other diseases that may cause pain in the thigh and leg. Where the calf is the part mainly affected one must think of thrombosis of the femoral vein, but this can be excluded by digital examination of the vessel at the groin, even if the complaint should be too recent to have caused œdema of the ankle. Disease of the hip-joint can be put out of consideration by the fact that neither pressure on the trochanter, nor forcing the head of the femur against the acetabulum, gives rise to pain; and disease of the sacro-iliac synchondrosis by the fact that no tenderness is elicited by tapping the articulation, or by pressure of the two ilia together. Advanced cases, in which the patient limps in walking and has wasting of the muscles, are very likely to be mistaken for spinal disease; this occurred some years ago in the case of a medical man whose fellow-

practitioners in his own neighbourhood all felt sure that there was something the matter with his vertebral column. Such disease is, indeed, very unlikely to have its effects confined for a length of time to one limb; but, on the other hand, when sciatica is at its height, the pain often radiates to the sciatic nerve of the opposite side. Even if one is satisfied as to the seat of the pain, one must still search carefully for local causes of irritation. In one instructive case a surgeon, feeling carefully along the course of the nerve, was fortunate enough to detect the presence of a bit of broken needle, the removal of which led at once to the cure of the patient.

Prognosis and treatment.—The duration of neuralgia in general and its amenability to treatment vary greatly in different forms of the disease, as well as in different cases of the same kind. The most protracted and obstinate form of all is Tic douloureux; most writers speak of it as incurable. Even this, however, is a very long time in wearing out the patient's life. Trousseau mentions a case in which it went on for thirty years. In the other varieties of neuralgia it is altogether exceptional for the disease to last more than a few months; but Anstie alludes to some instances of sciatica as defying all medical skill. In forming a prognosis one is to a great extent guided by the age of the sufferer; the older he is the more likely is the course of the disease to be prolonged. Recovery is generally gradual, and it is apt to be interrupted by relapses. Even after the pain is gone the affected part sometimes feels stiff for a long time, and its muscles are quickly fatigued by exertion.

The *treatment* of neuralgia is a matter which often taxes to the utmost one's patience and skill. Hygienic conditions must be carefully attended to; fresh air, regular bodily exercise, freedom from excitement, plenty of sleep, an abundant supply of wholesome nutriment, are each essential. Anstie laid special stress on the importance of a liberal diet, and particularly on the value of fat as an article of food. Whenever he could he made his patients take cod-liver oil; if the stomach revolted at that, he insisted on their eating butter, Devonshire cream, or sometimes olive oil, or even cocoa-nut oil. He strongly objected to allowing sufferers from neuralgia to have wine or brandy, excepting in very moderate quantities and with the meals, and all experienced physicians concur in his repeated protests against prescribing stimulants for the mere relief of pain.

Quinine in large doses is often of striking benefit, especially in trifacial neuralgia, and in cases which show periodic exacerbation.

When neuralgia particularly affects the lower jaw, and whenever it is connected with dental iritation, *butyl-chloraldehyde hydrate* ("croton-chloral") has sometimes striking curative effect, and is always worthy of trial. It often unmistakably succeeds, and often as unmistakably fails.

Fothergill gave *conium* in large doses, and not without success.

Ammonium chloride in full doses is believed, on excellent authority, to be an efficient remedy in certain cases.

Of all drugs, however, *arsenic* appears to hold the first place. Dr Fagge preferred the liquor sodæ arseniatis, because he had several times found that patients could take it without inconvenience who were attacked with diarrhœa and vomiting if they were placed on Fowler's solution. The liquor arsenici hydrochloricus may be used in combination with the tinctura ferri perchloridi, itself a remedy to which Anstie attached a special value.

Dr Ashburton Thompson has advocated the treatment of neuralgia by *phosphorus*. The formula to which he gives the preference is a solution of the drug in cod-liver oil; of this a fluid drachm, containing one twelfth of a grain, is administered every four hours. Phosphorus may be made into pills, and the Pharmacopœia contains directions for their manufacture; but it has been shown by Dr Rees that phosphorus pills are apt to pass through the intestinal canal without being dissolved. Dr Thompson gives a table of fifty cases of neuralgia treated by phosphorus, in several of which the effects of the remedy seem to have been remarkable; but he says that if decided results are not attained within three days it is useless to persevere.

Of late years *Antipyrin* has been much used for neuralgia, particularly facial neuralgia, and in many cases its effect is decided and complete. It seems to be of little use in sciatica, as perhaps might have been anticipated.

Apart from the pressure of gummata or other tumours on the nerve in the pelvis, it is probable that syphilitic neuritis may cause sciatica, and that full doses of potassic iodide and local mercurial inunction will effect a cure in such cases: similar treatment of gouty neuritis by colchicum has been also already referred to.

Galvanism is often very valuable in the treatment of neuralgia. One of the poles of a constant-current battery may be placed close to the spine of the affected side, or near the roots of the painful nerves, the other being applied upon the various "tender points" in succession, or being perhaps immersed in a vessel of water into which the hand is also dropped. A "descending" current is usually employed, the positive pole being put nearer to the centres than the negative one, but reversal of the poles seems to make no difference in the result. A good example of the effect of this form of electricity is afforded by a case related by Anstie in the fourth volume of the Clinical Society's 'Transactions.' A woman had for nearly five months suffered from cervico-brachial neuralgia, which lasted for several hours each day, and had defied all kinds of medicinal treatment. The very first application of a battery of from ten to fifteen cells arrested the pain; the attack which followed was much less severe than usual; and after thirteen days the complaint ceased to recur. The treatment was continued altogether for six weeks. Another case in which great relief was afforded was read to the Clinical Society at the same time by Dr Buzzard.

Faradisation of the nerve is rather injurious than beneficial, but the application of a powerful current to the skin by means of the electric brush is said to be sometimes useful as a mode of severe *counter-irritation*. Its action is similar to that of *blisters*, which are undoubtedly of great value in many cases. Anstie recommended that they should be placed not upon the painful part itself, but close to the spine at the level of the affected nerves. Even in the desperate tic douloureux of old age he sometimes found that a blister applied to the nape of the neck removed the pain entirely for a long time. But in sciatica he obtained better results by placing flying blisters over the nerve-trunk in the gluteal region. Mustard plasters, chloroform liniment and other rubefacient applications are only serviceable in mild cases.

Acupuncture over the sciatic nerve, and *deep injections* of morphia in that region, are powerful and frequently successful measures. Formerly it was the practice to divide the infra-orbital nerve in severe cases of neuralgia, and when the relief was found to be only temporary, to excise a piece: the writer saw this done by Nélaton in 1863. But even then the proximal part of nerve

grows out and reunites, so that the operation has fallen into disuse.* A more recently introduced practice is *stretching* the affected nerve, either by cutting down upon it and forcibly pulling the trnnk out of its bed, or by forcible flexion of the thigh upon the pelvis with the knee extended: both methods are reported to have been successful in a few cases, but neither is without risk of injury.

When all attempts at treatment by local measures or by drugs specially indicated have failed, we must fall back on the remedy which would naturally first suggest itself for so painful a disease as neuralgia—*opium*. One should be very cautious in administering it when there is any hope of the ultimate subsidence of the complaint; but in cases of incurable tic douloureux Trousseau employed opium with no little success, increasing the dose boldly until sometimes as much as a quarter of an ounce or even half an ounce of laudanum was taken daily. In a few instances the result was more than a palliation of the patient's misery. The frequency and severity of the attacks of pain were lessened, so that after a time the drug could be discontinued; and although a relapse occurred a few weeks later, the interval of ease was a great gain; sleep had been obtained and food had been taken, which had before been almost impossible, so great was the suffering caused by mastication.

In many cases the administration of opium by the mouth disorders the digestive organs. Hence the subcutaneous injection of morphia is preferred, for it is attended with no such ill effects; and of late years this method of treating neuralgia has been extensively employed. The quantity should be very carefully regulated; not more than a fifth of a grain (two minims of the Pharmacopœial solution) should be used on the first occasion; in mild cases it is even well to begin with one tenth of a grain. If relief is not afforded by such doses, larger ones may be tried; a quarter of a grain, half a grain, even a grain, is commonly injected under these circumstances; and sometimes much greater quantities still. One seldom has to use the syringe oftener than twice in the twenty-four hours; but Anstie laid stress on the importance of performing the operation as early as possible after the commencement of an exacerbation of the pain. It seems to be almost a matter of indifference whether the morphia is injected at the seat of pain or at any other part of the body, except so far as concerns the effect on the patient's imagination.

The effect of subcutaneous injection of morphia is often marvellous. Suffering which had been almost intolerable is removed, as by magic, within a few minutes. And this is not infrequently the first step towards the complete cure of the disease. It was so, for instance, in the severe sciatica of which Dr Lawson was himself the victim, and in which other plans of treatment had been tried without the least good result.

This method is not, however, free from evils of its own. Dr Oliver has related in the 'Practitioner' a case in which immediately upon the injection the patient cried out in great alarm, the pulse became very small, the face red, and the eyeballs prominent. Brandy was given, and in about half an hour these symptoms passed off. It is thought that the alkaloid may have been thrown directly into a small vein. But such an accident is excessively rare.

A much more serious risk is that of setting up a "morphia habit,"

* See Mr Bowlby's Astley Cooper prize essay on "Diseases and Injuries of Nerves, and their Surgical Treatment" (1886).

a peculiar state of depression and irritability, which can be relieved by nothing but a fresh dose. There is also reason to fear that the remedy itself sometimes renders the pain more intense than before, or at least diminishes the intervals between the exacerbations. Even when the original disease is cured patients sometimes experience great difficulty in discontinuing injections of morphia to which they have been accustomed; a vigorous effort may be needed, and the endurance of much discomfort and even misery for several days. For this reason, as well as for others, the syringe should not be entrusted to the hands of the sufferer himself, nor even to those of a relative or servant, unless perhaps in incurable cases. Anstie, however, laid stress on the fact that the evils connected with the establishment of a morphia habit never arise when the dose is kept below a certain point. In a valuable paper in the 'Practitioner' he insisted stongly on the importance of "economy" in the use of the alkaloid; and he related the case of a lady, who for three years had enjoyed a complete immunity from severe sciatica under the daily use of a dose of morphia, which was at first one twelfth of a grain, and was never raised above one fourth.

PERIPHERAL PARALYSIS.—Many points in regard to the causes and symptoms of paralysis from lesions of the nerve-trunks are the same, whatever parts of the body are their seat. It is convenient to take the nerves of the arm by way of illustration, because the movements performed by its several muscles are more distinct and definite than those of the individual muscles of the leg, and their functional integrity is accordingly more easy of determination.

Injuries of the *brachial plexus* may be followed by loss of power and of sensation in the whole upper limb. The surgeon sees cases in which this occurs as the result of severe accidents in which the shoulder-joint is dislocated, or the humerus or scapula fractured. But similar symptoms not infrequently follow pressure upon the nerves, or an injury so slight that its occurrence, especially in a child, may be altogether overlooked. Thus Paget ('Med. Times and Gaz.,' 1864) mentions the case of a boy whose left arm, while he was still an infant, was violently pulled by a little brother; the limb appeared altogether powerless for long time afterwards, and it remained permanently weak and much smaller than the other one. The employment of force to reduce a dislocated shoulder has sometimes been attended with like consequences; so also the pressure of a crutch, tying the arms of a prisoner with a cord, and carrying certain large vessels with handles through which the arm is passed, as among the water-carriers of Rennes. "Crutch paralysis" is not uncommonly seen in hospital practice in London; and the patient is often unaware of its cause. A similar effect may also be produced by lying on one side, with the weight of the body resting upon the arm; or, more often, by sleeping with the arm across the back of a chair. But in most instances of this kind the sensibility of the patient has been blunted by drink, and hence they used to be known in the hospital as "Sunday morning" paralysis. When the cause is doubtful, the axilla and neck must be carefully examined, lest an aneurysm, exostosis, or other tumour should be overlooked. Some writers believe that the brachial plexus is sometimes affected by external cold, as we shall presently see to be the case with the facial nerve; but this is doubtful. Mr Salter has related ('Guy's Hosp. Rep.,' 1868) two cases, in each of which caries of a wisdom-tooth, beside causing severe pain in the arm, led also to partial "reflex" paralysis of the

muscles, so that the patients could not grasp objects nor raise the hand to the head, nor hold a fork at dinner. In both cases all the symptoms vanished as soon as the tooth had been extracted or a few hours later.

It is exceptional for the whole of the brachial plexus to be paralysed at once by any of the above causes; and the loss of power may often be limited to the muscles supplied by a single nerve. In such cases the interpretation of the symptoms may be so obvious that no anatomist could possibly misunderstand them. But sometimes they require careful study.

Special motor paralyses.—Particular interest attaches to paralysis of the serratus magnus muscle. The *posterior or long thoracic nerve* which supplies it leaves the plexus at so high a point that it is never involved when the cause is the pressure of a crutch, or sleeping upon one arm. But it may be affected by a blow upon the shoulder; by carrying a heavy weight upon the shoulder; or by over-exertion of the shoulder-muscles, as in the case of mowers, puddlers, cobblers, or ropemakers. Sleeping on damp ground and exposure to draughts are also said to have given rise to it.

The principal symptom is an alteration in the position of the scapula. Even when the shoulder is at rest, with the arm hanging down, the scapula, as a whole, is drawn slightly upwards and inwards, and has its inferior angle tilted, so as to be nearer to the vertebral column than the rest of its posterior border. But what is more characteristic is that this posterior border stands off a little from the part of the back on which it should rest, forming a "wing-like" (pterygoid) projection. These peculiarities are greatly exaggerated when the patient is told to perform certain movements. Thus if he is directed to lift his arm straight over his head, he finds himself unable to raise it above the level of the shoulder, because the necessary rotation of the scapula by the serratus cannot be effected; but when once another person has moved the bone to the proper position for him and fixed it there, he acquires the power of lifting the limb to whatever height may be desired. During the attempt to raise the arm, the scapula, if left to itself, moves further than ever towards the spine; and where both serrati happen to be paralysed together the two bones may actually come into contact at their inferior angles. If the raised arm is brought forwards the "wing-like projection" becomes greatly augmented, the posterior border of the scapula standing off so as to leave a deep hollow. Another symptom, according to Dr Poore ('Clin. Soc. Trans.,' viii), is an alteration in the shape of the chest on the affected side, as shown by the cyrtometer. He finds that in a healthy person, when the arms are thrown horizontally forwards, the chest becomes flattened in front, and its transverse diameter is increased. Where there is paralysis of one serratus no widening occurs on that side.

An affection of more frequent occurrence is paralysis of the muscles supplied by the *circumflex* nerve, among which the *deltoid* is the chief. This, too, may result from direct injury to the shoulder. According to Erb it is sometimes caused by "rheumatic" affections of the articulation. One must, however, bear in mind that osteo-arthritis (to which disease Erb probably refers) is commonly attended with destruction of the long tendon of the biceps, and that unless this structure is perfect the arm cannot be raised; while inability to lift the arm from the side is also the principal symptom of paralysis of the deltoid. It may be thought that a sufficient proof of paralysis would be found in atrophy of the muscle, which, indeed, is often so marked that a deep groove is formed between the acromion and the head

of the humerus. But a considerable degree of wasting may be the result of mere disuse when the joint is diseased.

Paralysis of the *musculo-cutaneous* nerve is indicated by inability to flex the elbow-joint, the biceps and brachialis anticus muscles being paralysed. It must be borne in mind that the supinator longus (which receives its supply from another source) is also a flexor, and the patient must therefore be told to keep his hand supinated while the power of the other muscles is being tested.

Among the nerves which send filaments to the hand and fingers the *musculo-spiral* is much more apt than the other two to be separately affected. In a considerable proportion of the cases of paralysis due to the pressure of a crutch, or to lying on one side during the deep sleep of intoxication, the musculo-spinal nerve suffers alone; and as in the latter case the triceps often escapes, it is probable that the nerve undergoes compression where it is winding round the humerus, and after it has given off the branches to that muscle. The extensors of the wrist, of the two joints of the thumb, and of the metacarpo-phalangeal joints of the fingers are the chief other muscles supplied by this nerve; and accordingly one symptom of paralysis of it is a flexed condition of these joints, with inability to straighten them; the two remaining joints of the fingers being nevertheless capable of extension by the interossei and lumbricales, provided that the metacarpo-phalangeal joints are held up by another person. Another consequence of the loss of power in the extensor muscles of the wrist is impairment in the extent to which the fingers can be *flexed* upon the palm. The paralysis of no other nerve interferes so much with the motions of the hand as that of the musculo-spiral.

Isolated paralysis of the *median* (or of the ulnar) nerve is more commonly due to a wound or injury at the elbow, in the forearm, or at the wrist, than to any affection of the brachial plexus above. The symptoms, in the case of the *median* nerve, are inability to use the flexors of the wrist and fingers, the metacarpo-phalangeal joints being alone capable of flexion by means of the interossei. Indeed, the excessive action of these muscles is apt to cause an over-extension of the two phalangeal joints of the fingers, and especially of the index finger.

On the other hand, when the *ulnar* nerve is paralysed the muscles of the little finger and the interossei are more markedly affected than any others. The fingers cannot be abducted nor adducted, and the patient is unable to flex the metacarpo-phalangeal, or to extend any of the phalangeal joints of the fingers. There being nothing to antagonise the traction excited by the common extensor and flexor muscles, the joints in question become distorted, so that the last two phalanges are over-flexed, while the first phalanges, on the other hand, are over-extended. Accordingly, the prominences of the knuckles are replaced by hollows on the back of the hand, while they project towards the palm, and are the more noticeable there because the interossei and two of the lumbricales muscles are atrophied. The fingers of a hand so affected are often compared to the claws of a griffin—*le main en griffe, Klauenhand.*

The production of deformities, in affections of the nerve-trunks, by contraction of the muscles which are physiologically the antagonists of those that are paralysed, has not hitherto been mentioned; but it may occur in every form of these affections, and often complicates the symptoms considerably. On the other hand, at advanced periods of cases, the paralysed

muscles may waste and shorten, so as to produce distortions of precisely opposite characters.

The anatomical distribution of the nerves is not strictly adhered to in all cases of peripheral paralysis. Erb speaks of having seen several instances in which the deltoid, biceps, brachialis anticus, and supinator longus were chiefly, if not exclusively, attacked; and he throws out the suggestion that this depends upon an affection of the sixth cervical nerve where it is emerging from between the scaleni. In such patients the arm hangs by the side, and the elbow cannot be flexed. It is remarkable that a precisely similar affection was described by Duchenne in newly born children, as the result of traction or pressure upon the shoulder during birth. Erb has himself seen two cases of this kind.

Lastly, one must bear in mind that in exceptional cases a morbid process beginning in a single nerve at a particular spot is very apt to pass upwards along that nerve, and may afterwards extend to other nerves with which it is connected. Thus Dr Weir Mitchell relates the case of a man who received an injury to the nerve which supplies the pectoralis major; on the third day he was attacked with pain in the course of the median and musculo-cutaneous nerves, and the muscles to which they are distributed subsequently became paralysed and wasted. Another patient bruised his ulnar nerve at the bend of the elbow, and about five months afterwards the flexor muscles of the wrist became affected with paralysis, those supplied by the median nerve, as well as those supplied by the ulnar. These, however, were probably examples of peripheral neuritis.

The reaction of degeneration.—Cases of local paralysis due to lesions of the nerve-trunks are all examples of "peripheral paralysis," and the electrical reactions of the affected nerves and muscles present characteristic modifications. These were first minutely studied by Erb and Ziemssen.

Let us suppose that a nerve-trunk is cut across. The result is that throughout the whole length of the nerve and its branches below the affected spot (so far as one can test them without at the same time stimulating the muscles) its excitability undergoes a progressive diminution, both to the make and break of galvanic currents, and to the rapidly alternating faradic currents from an induction coil. In the course of the second week it is entirely extinguished, so that not the slightest contraction can be produced by the application of either form of electricity to the nerves. But the reactions of the paralysed muscles are very different. They, too, fail to respond to a faradic current; but when a galvanic current is employed they contract much more readily than under normal circumstances to the stimulus of opening or closing. The method of determining this fact is first to ascertain what number of cells of the battery are required to excite contractions in the corresponding muscles of the healthy limb; we then perhaps find that only half that number is needed to excite contractions in the muscles supplied by the injured nerve. Indeed, they can often be thrown into vigorous action by a current which is too feeble to be felt.

Moreover, there is what is termed a "qualitative" change, *i. e.* the order in which the two poles excite contractions is altered. According to Pflüger's law, stimulation depends upon rise of catelectrotonus or fall of anelectrotonus (*i. e.* in either case the passage of a segment of nerve from a lower to a higher degree of excitability); the descending current has

greater exciting power than the ascending, and closing or making than opening or breaking the galvanic current. Accordingly, the order in which currents of successively increased strength produce contraction in the muscle supplied by the motor nerve stimulated is as follows:*

	CC	AO	AC	CO
Weak current causes . .	c			
Strong current causes . .	C	c	c	
Very strong current causes	C′ or T	C′	C	c

The rule may be shortly remembered thus:—With increasing strength of galvanic current the order in which contractions appear is C.C.C., A.O.C., A.C.C., C.O.C.†

When, however, a muscle is paralysed by severance of its motor nerve in any part of its course, or by destruction of its anterior root, or of its corresponding large ganglion-cells in the anterior cornu, and when this has lasted for a week, not only is the muscle less excitable when the "motor point" of its nerve (*i. e.* the place where it becomes superficial and is most favourably stimulated) is excited by the induced (faradic) current, not only is it *more* excitable when the same point of its nerve is stimulated by the make or break of the direct (galvanic) battery current, but the above physiological order is altered.

So far from contraction at the moment of closure with the cathode (C.C.C.) being now the most marked effect, there is often as much or even greater contraction when the circuit is completed with the anode; while instead of cathodal opening contractions (C.O.C.) being the last of all to appear, they may precede the anodal opening contractions (A.O.C.). Accordingly the normal order for contractions with currents of increasing strength given in the above table is altered, and instead of C.C.C., A.O.C., A.C.C., C.O.C., we have A.C.C. before C.C.C., and C.O.C. before A.O.C.; *i. e.* the anodal closing contraction is for equal currents stronger than the cathodal, and the cathodal opening contraction is for equal currents stronger than the anodal.

This is called the Reaction of Degeneration.

* Here C.C.c. means that a small Cathodal Closing contraction is produced by a weak current. The current is descending, and the stimulus is the rise (in this case from zero) of catelectrotonus on closing (making) the galvanic circuit. A.O.C. means that an ascending galvanic current produces an Anodal Opening (breaking) contraction, the stimulus being the fall of anelectrotonus (to zero). A.C.c. or A.C.C. means that making contact again with the ascending current will, if it is as strong or stronger, produce a slight or a marked Anodal Closing contraction. Lastly, C.O.c. means that breaking contact with the descending current will, if it is strong enough, act as a slight stimulus and produce a Cathodal Opening small contraction.

† The German symbols used by Erb are Ka. for Cathodal, An. for Anodal, S. (Schleissung) for closure, O. (Oeffnung) for opening, and Z. (Zuckung) for contraction. These are wholly or partly adopted by some English writers. If it were important to avoid using the same letter for different words, it might be done by spelling Cathode with a K, and using Break and Make instead of close and open. The normal sequence would then stand: K.M.C., A.B.C., A.M.C., K.B.C. But in such matters whatever is most generally used and best understood is best.

It may be added that c. means a weak contraction, C′. a strong one, and T. a tetanic contraction, that > and < mean respectively *greater than* and *less than*, and that R.D. means the Reaction of Degeneration.

Lastly, the contractions themselves are slow and protracted, and resemble tonic spasms rather than the short clonic movements which occur in healthy muscles when stimulated by galvanic currents.

Little progress has hitherto been made towards the explanation of these remarkable facts. The seeming paradox that muscles insensible to powerful faradic currents should nevertheless respond to very weak galvanic currents has, indeed, been accounted for by Neumann, who has shown that it depends upon their requiring a current to pass for some length of time before they can react to it. Momentary galvanic currents, even when of considerable strength, are as inoperative as faradic currents themselves. But why the muscles should be incapable of responding to currents of brief duration, and why they should be sensitive to weaker galvanic currents than under normal conditions, we cannot at present say.

This, however, is established; that the peculiar reaction in question, as well as the loss of electrical irritability in the trunk of the nerve below the seat of injury, is coincident with and indicative of a remarkable series of degenerative changes which affect the structure of the paralysed nerve and muscle. Erb accordingly proposed the term "reaction of degeneration" to denote the presence of increased galvanic excitability in a muscle, when associated with diminished faradic excitability. Within a few days after the occurrence of any severe lesion of a nerve-trunk, the whole length of the nerve below is found to be greatly altered: the medullary sheaths of the fibres break up into fatty granules, and it is doubtful whether the axis-cylinders remains undestroyed. At the same time the neurilemma everywhere undergoes a greatly increased development; first it becomes crowded with corpuscles, and these presently develop into spindle-cells and fibres, so that the nerve-trunk itself becomes much denser and harder than before. In the muscles, too, similar changes take place. The fibres diminish in size, and their striation becomes indistinct; but their nuclei multiply, and the perimysium is crowded with cells, which after a time undergo development into fresh fibrous tissue. If the injury to the nerve should remain unrepaired the muscular fibres waste still further, and at length the whole substance of the muscles is converted into a whitish yellow, flattened mass of dense fibrous tissue, in which no striated fibres can be discovered. It often includes in its interstices a large number of adipose cells.

The cause of these curious changes is at present unknown. The easiest way of explaining them would be to attribute them to an extension of an inflammatory process along the nerve from the seat of injury. But, as Erb remarks, they ought not then to be confined to that part of the trunk which is to the peripheral side of the lesion, nor should they be traceable through a plexus or be accurately limited to certain fibres; nor should they occur simultaneously in distant muscles, or in those which are placed in the upper part of a limb. In some way they depend upon the separation of the affected structures from the nervous centres, in accordance with the law named after its discoverer, Dr Waller.*

* It is important to remember that this remarkable reaction of degeneration is not confined to the paralysis from injury to peripheral nerves now under consideration. We shall hereafter see that it accompanies paralysis dependent on lesions of the motor ganglion-cells of the anterior cornua of the cord and of their homologues in the bulb and mesencephalon. If, therefore, we speak of the R.D. as characteristic of "peripheral paralysis," we must extend the meaning of the latter phrase. The R.D. and the histological changes in the nerves which follow it are indicative of *severance of the nerve-fibres affected from their trophic centres, either by destruction of these ganglia, or by severance of the nerve in its course.*

It must not be supposed that the commencement of degenerative changes in the peripheral nerves and muscles is a proof that the injury of the trunk above is permanent and irremediable. On the contrary, nerves possess extraordinary powers of regeneration. Even after the muscles have for several weeks exhibited the reaction of degeneration it often happens that the connection between their nerves and the spinal cord is at length gradually restored. Erb has noticed in such cases very curious anomalies in the reactions of the nerves and muscles respectively to electrical and other stimuli. Nerves that have completely recovered the power of transmitting volitional impulses may still remain devoid of all excitability by faradic or galvanic currents; or if their regeneration should take place early, they may regain their sensitiveness to both kinds of current before the muscles have ceased to present the reaction of degeneration. That reaction, indeed, does not persist for any great length of time after the original injury. If the nerve fails to undergo repair, and the muscle-fibres begin to disappear, their excitability to galvanic currents quickly begins to diminish, and at length it becomes extinguished; and even when regeneration of the nerve does occur, the muscles commonly display a lessened rather than an increased galvanic irritability while it is going on, and for some time after it had been apparently completed.

On the other hand, it is only when the original lesion of the nerve-trunk is of a certain degree of severity that the reaction of degeneration presents itself. In the slighter forms of paralysis, such as that due to the pressure of a crutch, or to compression of the brachial plexus or musculo-spiral nerve during sleep, both the muscles and nerves often retain their normal irritability both to faradic and to galvanic currents.

Time of the reaction.—When a motor nerve is severed (to take the simplest form of peripheral paralysis), voluntary motion is, of course, at once and completely lost. For about the first week both muscle and nerve are less and less susceptible to all stimuli; but after a few days—while the galvanic and faradic excitability of the muscle, and the faradic excitability of the nerve continue to diminish, until after two or three weeks they are entirely lost—the galvanic excitability of the motor nerve rapidly increases with the other phenomena which accompany degeneration of the nerve-fibres and atrophy with degeneration of the muscle. In cases which recover, the faradic excitability of muscle and nerve returns as voluntary motive power is re-established, and the abnormal galvanic reactions of the nerve more gradually disappear. In cases which do not recover, the reaction of degeneration continues, though in slowly diminishing degree, for many weeks or months, until at last it also is lost, and the atrophied muscle responds to no kind of stimuli.

Anæsthesia.—Nerve-trunks possess sensory beside motor functions, and these too may be impaired by the same lesions which cause paralysis. Thus, if we still take the brachial plexus by way of illustration, we find that affections of its nerves may completely extinguish the transmission of tactile impressions from all parts of the limb to which those nerves are distributed, and may likewise render the patient unable to feel a prick or a cut, heat or cold, or the passage of a galvanic current. The resulting loss of common sensation is termed Anæsthesia, while the incapacity to feel pain is distinguished as Analgesia. They do not necessarily accompany one another. Mitchell relates two cases in which, without the slightest impairment of

the sense of touch, there was great diminution in the susceptibility to pain, one patient experiencing only a slight pricking sensation when a large needle was run into the palm, and the other being scarcely sensitive to the electric wire-brush. In ordinary cases, however, this instrument is a most delicate test for the presence of minute degrees of susceptibility to sensory impressions. The part to which it is applied must be perfectly dry, so as to oppose the current passing through to the underlying muscles and confine its effects to the skin. The numerous minute points of the dry brush help to the same result. Mitchell says that if no sensation can be produced by it one may generally conclude that the loss is absolute; but that on several occasions the use of it has saved him from despairing of cases which had seemed altogether hopeless.

On the other hand, there are all possible degrees of anæsthesia—to a point at which very careful investigation is necessary to show that the transmission of impression is not perfect. The best ways of detecting very slight anæsthesia are to bring the tip of a feather gently upon the surface of the skin, or to touch a single hair with a needle or the edge of a knife. If the patient can feel this on one side but not on the other, sensation is to some degree impaired on the latter.

A pair of compasses may be used after E. H. Weber's method, the object being to determine at what distance from one another the points are felt to be distinct. This "limit of separate perception" varies greatly in different parts of the skin under normal conditions, from 2·25 mm. on the extremities of the fingers to 77 mm. on the arm. But for each region there is an average, and any very considerable departure from it may be taken as proof that some perversion of sensibility exists. Or a direct comparison may be made between the opposite sides of the body in the individual whose case is being investigated. An improved form of the instrument is sometimes employed, in which the two limbs of the compasses slide upon a graduated bar; this is called the "æsthesiometer." Dr Weir Mitchell teaches that, to ensure the most correct results that are attainable, one must cover the patient's eyes, keep the part which is to be tested perfectly at rest, and apply the compass-points (which should be rounded) lightly upon the surface of the skin, but with equal force, at exactly the same time, and in a line bearing a definite relation to the axis of the limb. Experience has shown that it is useless to base precise numerical statements upon Weber's method. It often happens that widely different results are obtained from the same spot at an interval of a few minutes. All we can obtain are relative results, and these are after all what we most want.

It would be a great mistake to suppose that in affections of a mixed nerve-trunk the loss of cutaneous sensation is necessarily equal to the muscular paralysis. Very often, particularly when the disease or injury is of but slight severity, there is little or no anæsthesia, although the loss of power is complete; or sensation may be quickly regained while the motor power is being slowly recovered. Probably the sensory centres are readily affected by few nerve-fibres and by very feeble impulses, whereas a muscle is unable to respond unless the stimulus is conveyed to it by many channels at once. As Mitchell remarks, this accords with the well-known fact that by irritation of the ulnar nerve at the elbow sensation is far more readily excited than motion.

Lesion of a mixed nerve-trunk never produces anæsthesia, unaccompanied by motor paralysis.

Beside degrees of anæsthesia there are certain perverted sensations, conveniently grouped together as *paræsthesiæ*—numbness, tingling, burning, &c. These, however, except numbness or "pins and needles," which is the most constant effect of moderate compression of a nerve, are less frequent and less characteristic in cases of injury or disease of nerve-trunks than in spinal and cerebral diseases, and will therefore best be treated hereafter.

Pain.—A third symptom of paralysis of the nerve-trunks is pain. It is by no means constantly present, and, indeed, is wanting in most cases of ordinary peripheral paralysis. It commonly exhibits in a more or less marked degree the features of neuralgia, and is referred mainly to those parts of the skin to which the diseased or injured nerve is distributed. It is sometimes due to peripheral neuritis; and the trunk of the nerve may then, in thin persons, be felt to be swollen and exceedingly tender. In some cases it is periodic, returning every day at about the same hour, generally towards the latter part of the day. There is a special variety of it, to which Dr Weir Mitchell has given the name of Causalgia (καῦσις, cautery), on account of its burning character. This may vary in severity, up to the most unendurable agony, which the patient compares to a "red-hot file rasping the skin." In cases of peripheral paralysis due to wounds, this kind of pain seldom, if ever, comes on until the process of cicatrisation is beginning. Its most frequent seat is—in the upper limb, the palm of the hand; in the lower limb, the instep. Heat aggravates it, and allowing the limb to hang down has the same effect. It is relieved by moistening the skin, and two of Mitchell's patients always carried a bottle of water and a sponge, and would not allow the affected part to become dry, even for an instant. Others found some ease in walking, by pouring water into their boots. In course of time the severe suffering caused by this condition often leads to a general irritability of the nervous system, allied to hysteria. The patient may then complain of hyperæsthesia of the whole body, particularly when the surface is dry.

This peculiar kind of pain seems never to occur in parts which have been rendered altogether anæsthetic by the complete division of their nerves; nor does it accompany the subjective sensations that are so often referred to the distal ends of limbs which have been amputated. From these facts Mitchell argues that its immediate cause is some change in the peripheral extremities of the nerves, rather than in the trunks above.

Trophic changes.—That causalgia is due to a peripheral lesion is the more likely because the integument of the parts in which the pain seems to have its seat is liable to a special change, to which Sir James Paget first gave a name—that of *Glossy Skin* ('Med. Times and Gaz.,' 1864). The surface shines, as though it had been varnished. In Paget's words, "the fingers"—for they are most often affected—"become tapering, smooth, hairless, almost void of wrinkles, glossy, pink, or ruddy, or blotched as if with permanent chilblains." An eruption of small, pointed vesicles (somewhat like those of eczema) is also of common occurrence; or bullæ may form, which afterwards ulcerate; or painless whitlows, leading to shedding of the nails. Or, again, the nails themselves may become arched and incurved, and the skin may shrink away from their roots, leaving the sensitive matrix partly exposed.

Parts which are the seat of causalgia are slightly *warmer* than those on

the opposite side of the body; whereas the general effect of injuries of the nerve-trunks is to lower the temperature; sometimes, as in some cases of Hutchinson's, by as many as eight or ten degrees Fahrenheit.

Zona, or shingles, is the name given to a remarkable affection of the skin analogous to these results of lesions of trophic nerves. It will be considered in the last section of this work, among Diseases of the Skin.

Another occasional result of morbid conditions of the nerves of a limb is a painful *swelling of its articulations* which may go on to anchylosis, and greatly increase the deformity and the disablement experienced by the patient. The arthritic effects of injuries to nerves have been well illustrated by Mitchell; they are analogous to the affections of joints which occur in certain diseases of the spinal cord, and will be afterwards described as the arthropathies of Charcot. They are in the highest degree rebellious to treatment.

Erb also mentions, as sometimes following paralysis of the musculo-spiral nerve, a thickening of the *tendons* at the back of the wrist—a circumscribed painless swelling, as large as a hazel-nut, evidently due to their having been exposed to mechanical strain by the flexed state of the joint.

These various conditions appear to be sure indications of the existence of some disease affecting the nerves of the parts concerned. But they do not necessarily depend upon the same lesion. Paget mentions two cases in which glossiness of the fingers developed itself as the result of neuralgia after shingles; Mitchell relates one in which it was due to a chronic affection of the spinal cord; and some years ago the late Dr Moxon had in Guy's Hospital a remarkable case in which a precisely similar state of the fingers was caused by the pressure of a mediastinal tumour.

Diagnosis.—The recognition of paralysis from lesions of the nerve-trunks is seldom difficult for a good anatomist. Sometimes, indeed, progressive muscular atrophy in an early stage might be mistaken for peripheral paralysis, particularly if the deltoid muscle should be alone affected, or the interossei and the muscles of the little finger. The application of galvanic and faradic currents to the paralysed muscles would clear up the doubt in some cases, but not in all.

Having ascertained that the paralysis is of peripheral origin, one must search for all possible causes of compression of the nerves. Some years ago a woman came to Guy's Hospital complaining of numbness and loss of power in the right arm, which symptoms (she said) had already lasted six months; she was found to have a cancerous growth in the breast, which had extended to the axilla, and involved the nerves of the brachial plexus. One must also bear in mind the possibility that the paralysis may be "reflex," due perhaps to irritation from diseased teeth.

In the lower limbs the mistake most likely to be made is that of attributing to an affection of the spinal cord a paralysis really due to a pelvic tumour compressing the sacral plexus, or to a mass involving branches of the lumbar nerves. In 1876 a woman died in Guy's Hospital who for ten years had suffered from paralysis of the sphincters of the bladder and rectum, and for seven years from loss of power and sensation in the legs below the knee-joints, so that she was unable to walk, and could only crawl about on her hands and knees. The cause was found to be a large abscess in the pelvis, through which the cords of the sacral plexus ran; it was dependent on disease of the bone.

The *prognosis* of the different paralytic affections that may result from lesions of the nerve-trunks of a limb depends upon their nature and severity. Most of the cases that come under the care of the physician get well sooner or later, and one can do much by treatment to hasten their recovery. Thus crutch-paralysis commonly passes off in a week or a fortnight; that which follows compression of the nerves during sleep more often lasts from four to six weeks, and it may be prolonged for several months; that which is caused by severe stretching or bruising of the nerves, generally lasts more than a year, and may never be entirely removed. Even after very long periods improvement sometimes takes place. Mitchell says that only the careful notes previously made could have convinced him of the extent to which function had been restored, in some of the worst cases, at the end of three or four years.

As may be inferred from what has been stated above, most valuable aid in the prognosis of this form of paralysis is afforded by an examination of the electrical reactions of the affected parts. In cases which are to terminate rapidly in recovery, the muscles and nerves retain their normal irritability; in those which are to run a protracted course, the muscles present the reaction of degeneration; while in cases which are incurable, susceptibility to every form of galvanic stimulus is extinguished.

Treatment.—Electricity is useful, not only as a guide to prognosis, but also in treatment. There is, indeed, still much uncertainty as to how it acts, but all writers are agreed that it is beneficial. Sometimes its effects are extraordinary. After a single application of faradic or galvanic currents the patient may suddenly find that he can perform movements which he had for weeks or months been unable to accomplish. But in such cases it may perhaps be assumed that the regeneration of the affected parts was already far advanced—that they were, in fact, on the brink of recovery—independently of any treatment. At earlier periods the action of electricity is generally less striking, and an apparent success is still less capable of bearing a critical scrutiny. Mitchell, indeed, speaks strongly of the importance of the use of faradic or galvanic currents at the earliest possible moment. As regards the choice of one form of electricity rather than the other, he adheres to a well-known rule which has been laid down by several other writers, namely, that whichever current is found to produce muscular contractions most readily should be used. It has been thought that by stimulating the muscles to contract one helps in keeping them well nourished, besides possibly doing something towards opening up the path for volitional impulses. But Erb maintains that if the reaction of degeneration is present one cannot by galvanisation hasten the recovery of motor power, although he admits that when recovery has once begun its progress may be accelerated.

In employing galvanisation in the treatment of paralysis from an affection of a nerve-trunk one should use the "labile" method. The anode is placed over the plexus above, or on some convenient "indifferent" spot, and the cathode is then slowly moved over the skin, covering each of the affected muscles and nerves in turn. The strength of the current should be such as to excite distinct muscular contractions, but not to cause more than a slight sensation of heat, and a little redness of the skin. Its application should be continued for about ten minutes every or every other day.

If the faradic apparatus be chosen, its two electrodes should be

held in one hand between different pairs of fingers, and they should be placed in succession over the various muscles at a little distance from one another.

Another method of treatment on which Mitchell lays great stress is that of shampooing the affected parts, or (as it is termed) "massage." Persons are trained to perform this manipulation, which requires strength and endurance as well as gentleness, for it ought to be continued for an hour at a time. The limb should first be immersed in a hot bath. Afterwards every part of the skin, so far as the paralysis extends, should be lightly pinched and tapped, and moved to and fro on the tissues beneath. Then the joints are to be moved in turn, and, lastly, the muscles must be gently kneaded and rolled, the power employed being gradually increased. Mitchell says that at the close of the sitting the temperature of the limb is raised by 1° or 2° Fahr., that the muscles are less flabby, and respond more readily to faradisation, and that the skin is sometimes intensely reddened. The patient feels refreshed and sleeps better. It should be repeated every day. A further proof of the efficacy of massage is that when it is carried on for too long a time it sometimes causes lumbar pain, headache, nausea, and exhaustion.

For persistent anæsthesia Mitchell recommends the application of a rather strong faradic current by means of the electric brush. After two or three sittings he has commonly found sensation beginning to return. He has also employed as counter-irritants rags dipped in hot spirits of turpentine and covered with oiled silk. This affects patients very differently, causing unbearable pain in some, while others scarcely feel it.

He quotes the case of a man who had lost sensation in the whole arm as the result of a fall on the shoulder, and who completely recovered after his arm and back had been severely blistered by the sun.

Causalgia may to some extent be relieved by dressings with cold water constantly renewed. The injection of morphia into the affected part is also useful, but Mitchell seems to rely mainly upon the repeated application of blisters. Sooner or later this form of pain almost always subsides.

CRANIAL NERVES.—The account above given of paralysis of spinal nerves is applicable, *mutatis mutandis*, to the cranial nerves likewise. But the latter possess functions which, when disordered, give rise to special symptoms. We will therefore discuss first the disorder of the *motor* cranial nerves (the facial, the nerves of the ocular muscles, and the hypoglossal), then those of the *sensory* nerve of the face (the fifth), and lastly, those of the two *nerves of special sense* (the olfactory and gustatory), which are still left within the province of the physician.

FACIAL PARALYSIS.—The motor division of the seventh nerve—the *portio dura*, or facial nerve—is very liable to affections which destroy its conducting power, and paralyse the muscle which it supplies. This is known as facial paralysis, or *Bell's palsy*, from Sir Charles Bell having discovered its pathology in 1838.

Ætiology.—Of the causes that may give rise to this disease, the most frequent is the direct action of cold upon the side of the face. It may result from sitting at the open window, whether of a room or of a railway carriage, sleeping near a damp, cold wall, or with the face exposed

to a draught of air,—even when the face is only chilled along with other parts of the body, as in a patient of Sir Thomas Watson's who walked about the streets for some days without shoes or stockings during a thaw. Such cases are spoken of by some German writers as "rheumatic," according to that wide use of the term which really deprives it of meaning. It is supposed that the trunk of the nerve becomes affected with a slight inflammatory swelling, which (perhaps by extending into the stylo-mastoid foramen) leads to compression of its fibres. The comparative rarity of similar paralyses of the spinal nerves from cold may depend on the larger size of the intervertebral foramina, and on their greater distance from the exposed portions of the nerves.

Inflammation or tumours of the parotid gland, swelling of the cervical glands, wounds of the cheek, and pressure of the forceps in instrumental delivery, are the chief other causes that may affect the nerve beyond the aqueductus Fallopii.

In its course within that canal the portio dura is liable to be involved in the severe forms of disease of the petrous bone, usually caries and necrosis. In fracture of the base of the skull, the nerve may be torn across. Dr Moxon has recorded ('Path. Trans.,' vol. xx) a case in which a clot of blood was found compressing and destroying this part of the nerve. It seems probable that a similar condition, resulting from the rupture of some small blood-vessel, was present in an oft-quoted case of Sir Charles Bell's, in which facial paralysis followed a box on the ear; and also in one, related by Sir Thomas Watson, of a man who developed facial palsy within three hours of having a fall in which he struck his hip and his elbow, but not his head.

On the cerebral side of the internal auditory meatus, the facial nerve may be implicated in tumours and other diseases of the base of the skull; or its origin in the pons may be affected. As a rule, such cases are distinguished by other nerves being involved, or by further symptoms of cerebral disturbance. But the author met with an instance in which simple paralysis of the right facial nerve, in a man who died of granular disease of the kidneys, was found to be caused by a minute spot of softening which existed in the pons, rather to the left of its centre, with a cyst of the size of a pea; and Dr Gowers has "seen two cases of seizure, evidently apoplectic, in which the only paralysis that followed the seizure was seated in the muscles supplied by the portio dura."

Partial implication of the facial muscles is common in ordinary hemiplegia; and it is a constant feature of bulbar paralysis. In one remarkable case facial paralysis was the earliest symptom of tubercular meningitis.*

The symptoms of Bell's paralysis are very striking, and present many points of interest. When the affection is developed to the fullest possible extent, the patient is altogether unable to move the muscles supplied by one facial nerve. Whether he frowns, or smiles, or laughs, one side remains

* I have myself had a patient who was attacked with Bell's paralysis twenty-four hours after the development of an eruption of herpes zoster on the same side of the face. He came to me about seven weeks afterwards; the loss of power to move the facial muscles was then almost complete, and the "reaction of degeneration" was found to be present when the electrical test was applied. The purple scars caused by the eruption were still visible. No indication of any disease affecting the seventh nerve could be discovered; and I was inclined to regard the paralysis as reflex. He slowly recovered, after the lapse of several months.—C. H. F.

expressionless; the forehead is unwrinkled, no creases appear round the eye, the cheek and chin are marked by no dimples, the angle of the mouth remains in the same position as before. When he tries to close the eyelids forcibly, those on the paralysed side are motionless, a condition pedantically called lagophthalmos (hare's-eye); but since there is a physiological association between forced closure of the eye and elevation of the globe, the latter action, which is effected through the third nerve, still goes on; and the eyeball is involuntarily turned upwards, or upwards and inwards, until the pupil is hidden beneath the upper lid. The actions of spitting, whistling, and blowing are impossible; the sides of the mouth cannot be pursed up; the cheek is not held close to the teeth by the buccinator muscle, and bulges out with expiration of the breath. For the same reason, when the patient masticates, the food cannot be retained within the space between the jaws, and collects outside the teeth on the affected side, so that he has to dislodge it with his finger, unless he keeps his hand pressed against the cheek while he is eating. In speaking, he pronounces the labial consonants indistinctly—*p*, *b*, *f*, *v*, and *m*.

The degree to which the face is distorted when in repose varies considerably in different cases, even among those in which the loss of voluntary power is complete. In some patients the mouth is drawn far over to the opposite side, the eye stares fixedly, and the countenance has a constant and most comical aspect. This seems to be due to a contraction of the antagonist muscles analogous to that which causes distortion of the fingers when the interossei are paralysed. But perhaps one element in the result is an absolute loss of tone in the affected muscles, which occurs only when the nerve is completely destroyed, as in cases of necrosis of the temporal bone; for in most of the so-called "rheumatic" cases the patient's features are but little disturbed while they are at rest, so that at a cursory glance one may scarcely notice that anything is amiss with him. Even when he is altogether unable to close the eye, the palpebral aperture may appear but little wider than on the unaffected side, and the *tensor tarsi* muscle may still be able to keep the lachrymal puncta in contact with the globe, and to prevent the tears from running down over the cheek, as they do in the most extreme forms of the disease. Perhaps during sleep, when the levator palpebræ is relaxed, the eyelids may approach one another more nearly than would be expected from the patient's inability to close them when he is awake, with the levator acting in opposition to his efforts. In this way one may perhaps find an explanation of the not infrequent absence of inflammation, which one would expect to be a necessary result of particles of dust settling upon the exposed eyeball. As is well known, the conjunctiva is very apt to become inflamed under such circumstances, and the cornea may lose its transparency or ulcerate; but Valleix had a case of facial paralysis of twenty years' duration in which no such results took place. In the daytime, as Trousseau remarks, the patient is able to compensate for the failure of movement in the eyelids by bringing the globe into various positions so as to wipe it upon different parts of their inner surfaces; or he may push down the upper lid with his finger.

Among the indirect effects of facial paralysis, impairment of the sense of *smell* is sometimes mentioned; and it is attributed to a dry condition of the corresponding nostril, which results from the escape of the tears over the cheek.

A much more frequent symptom is a perversion of the sense of *taste*. Trousseau, for example, speaks of a man who said that his food tasted like "salt plaster;" and other patients have experienced a subjective metallic or sour taste in the fore part of the tongue on the affected side; or a loss of power to detect acid, sweet, or saline flavours. This appears to be directly due to interruption of the conducting power of a branch of the seventh nerve, the chorda tympani. It is also said that the secretion of saliva may be diminished from the same cause.

The sense of *hearing* is often abnormally acute; there is an augmented sensibility for all musical notes and sounds, the patient hearing a watch at a greater distance from his ear on the affected than on the healthy side; there is also an increased capacity for the detection of sounds of very low pitch; and there may be a subjective sensation of hearing an acute sound. This state of the auditory sense has been (barbarously) named "oxyakoia." Brown-Séquard propounded the theory that it is due to hyperæmia of the auditory nerve consequent on paralysis of its vaso-motor nerves. But Lucæ has since shown that it is the result of paralysis of the stapedius muscle, which receives a branch of the facial nerve; its antagonist, the tensor tympani, being no longer opposed, keeps the membrane too much on the stretch ('Berl. klin. Woch.,' 1874, Nos. 14, 16). Auditory hyperæsthesia, therefore, should never occur in facial palsy of peripheral origin.

Another branch of the facial nerve, which is often affected in Bell's paralysis, is that which goes to the soft palate. The late Professor Sanders showed ('Edin. Med. Jour.,' 1865) that there is then "a vertical relaxation or lowering of the corresponding half of the velum, with diminished height and curvature of the posterior palatine arch," a condition which he believes to be due to loss of power in the levator palati muscle. In certain cases the uvula is turned to the paralysed side; but this seems not to be constant, and it possesses little significance, inasmuch as lateral deviation of the uvula sometimes occurs in healthy persons. If the levator palati is paralysed, it would follow that the lesion of the portio dura must be on the cerebral side of the geniculate swelling of the nerve in the petrosal bone. But the symptom is more often looked for than seen.

Diplegia facialis.—The right facial nerve is as liable to paralysis as the left. It sometimes happens that *both nerves* are paralysed in the same patient; the symptoms are then to a certain extent peculiar, so that such cases have been dignified with the special name of "diplegia facialis." The chief point is that there is no distortion of the features under emotion of any kind. The face remains without expression, and, as Romberg put it, the patient laughs or cries behind a mask. Double facial paralysis may be caused by a new growth or gumma, involving both nerves at the base of the skull; but more frequently it is due to disease affecting the two petrous bones separately, or to the action of cold upon both sides of the face in succession.

Diagnosis.—This is seldom difficult when facial palsy is fully developed. One must not omit to notice whether any other nerves beside the seventh are paralysed, for if such is the case there is reason to suspect the presence of some new growth or syphilitic disease at the base of the skull. Even when the loss of power is very slight and incomplete, one can for the most part decide its peripheral origin by a little failure of expression limited to one side of the face, and by a narrow chink remaining between

the closed eyelids, for these symptoms do not accompany a partial paralysis of the facial nerve from disease of the brain.

Course.—The onset of Bell's paralysis is sometimes gradual, sometimes sudden. Among hospital patients it often happens that what first attracts the patient's notice is his finding himself unable to spit or to whistle; or he may find his face "all on one side" when he gets up in the morning.

The subsequent course of facial palsy varies greatly. When due to destruction of a considerable portion of the nerve, as in cases of necrosis of the petrous bone, it is of course permanent and incurable. Although recovery is possible after an injury, such as the division of the nerve in a surgical operation, yet this seldom occurs before the lapse of several months, and it is apt to remain incomplete. Even where the affection is the direct result of exposure to cold, it may last from four to six months; but sometimes it gets well much more rapidly, the patient beginning to regain power over the muscles at the end of ten or twelve days, and recovering completely within a few weeks.

Prognosis.—It might be expected that one of the best indications of the probable duration of the affection would be the presence or the absence of paralysis of the proximal branches of the facial nerve, the chorda tympani, and those to the stapedius and palate. Dr Sanders, however, maintained that the prognosis is not more unfavourable in cases in which the last-named branch is implicated. The question is not of much practical importance, because we seem to have in the application of electricity a method of determining the gravity of an attack of facial paralysis from the first.

This point has been carefully worked out in Germany by Brenner and by Erb. From their observations it appears that in the *mild* form of the affection, which recovers in two or three weeks, the muscles and nerves of the paralysed side of the face react both to galvanic and to faradic currents exactly in the same way as on the healthy side. In only a single instance of rapid recovery could Brenner detect a slight and transient diminution of excitability to both kinds of current. But in the *severe* form (which includes a large proportion of those cases which are due to the direct action of cold) those peculiar effects are observed which have been described above as the "reaction of degeneration." Indeed, it was in a case of facial paralysis that this reaction was first noticed by Baierlacher in 1859. The prognosis is then always so far unfavourable, that no improvement is to be looked for until two or three months have passed, that a complete recovery seldom takes place before the lapse of another period of equal duration, and that more or less weakness or stiffness of the affected muscles sometimes remains during the rest of the patient's life. Erb describes an intermediate form of facial palsy in which the excitability of the nerve is not completely lost, although the muscles present the characteristic sensitiveness to feeble galvanic currents with absence of faradic contractility; such cases, he says, recover in from four to six weeks.

In severe cases of Bell's paralysis *spasmodic affections* are observed at an advanced stage. When the patient is just beginning to recover voluntary power over some of the muscles, it often happens that the effort to induce contraction in one of them causes simultaneous movements in muscles of a different part of the face. He may wish to move his eyebrow or his eye, and he involuntarily draws his mouth to that side; he may intend to close his lips, and he finds that he also shuts his eye. In a patient who was under the author's care in 1877, the distortion of the mouth was so great when an attempt was made

to close the right eye, that the clinical clerk actually supposed the left side of the orbicularis oris to be paralysed. Hitzig, who has especially studied these curious phenomena ('Arch. f. Psych.,' 1872), notes that they sometimes occur while there is absolute paralysis (for all volitional efforts) of the muscles which are concerned in the associated movements. It seems difficult to avoid the inference that the motor impulse must find its way through the obstructed part of the nerve along the fibres which have regained their conducting power, and so reach the peripheral branches. But it would seem that the facial nucleus in the medulla oblongata is also in a condition of exalted irritability in many cases, for Hitzig has found that touching the affected side of the face sometimes gives rise to spasms which may even involve the muscles of the opposite side. In one case of facial paralysis, contractions actually extended to the muscles of mastication, and to those of the limbs. The occurrence of associated movements is commonly a precursor of the return of voluntary power over the paralysed muscles. They generally quickly disappear, but sometimes they seem to delay recovery, and (according to Erb) they have been known to last for as many as thirteen years.

On the other hand, when the paralysis is to be permanent, *tonic contractions* of some or all of the muscles often show themselves, which seem to have been described by Duchenne before they had attracted the notice of other observers. The result may be an elevation of the angle of the mouth, a deepening of the naso-labial groove, a narrowing of the palpebral aperture, or a general exaggeration of all the markings of the affected part of the face. The features are sometimes dragged over to such an extent that one might fall into the error of supposing that the healthy side was the one paralysed. Duchenne asserted that whenever in the course of facial paralysis some particular muscle recovers its tone earlier than one would have expected, one should be prepared for the supervention of tonic spasm in it. But this statement seems inconsistent with the fact that such spasms depend upon the occurrence of degenerative changes in the muscles themselves—a fact established by a case of Hitzig's, in which a patient who already had contraction of the orbicularis palpebrarum from a former seizure of Bell's paralysis was attacked a second time by the same disease, without the muscle in question undergoing relaxation.

Treatment.—This is still a doubtful matter. When the discovery was first made that the muscles in many cases exhibit an augmented susceptibility to galvanic currents, most observers assumed that the application of that form of electricity would cure the disease more quickly than the faradisation which had before been employed. But in 1869, Erb, after analysing the cases which had then been recorded, expressed the opinion ('Deutsches Archiv,' vi) that the "severe" form, in which alone the reaction of degeneration is present, cannot be materially shortened in its course by galvanism. According to him, the constant current is of little value until the conductivity of the nerves is re-established, although he believes that it then accelerates the recovery of voluntary power over the muscles. He recommends that the anode should be placed behind the ear, and the cathode moved over the paralysed half of the face; or else that the two poles should be placed one over each mastoid process, the affected side receiving the anode. In mild cases he says that each application of the current is usually followed by increase of voluntary power over the muscles. It must not be forgotten that Duchenne believed that he attained still better results from

faradisation; he speaks of cases which had lasted for years, and which were, without exception, cured or greatly relieved by this procedure, although all other treatment had failed. So impressed was he with its potency, that he regarded it as capable of inducing secondary spasms, and consequently advised that when the muscles began to regain their tone the intermissions of the battery should be reduced in frequency to not more than four in the second. He did not indeed recommend that faradisation should be laid aside altogether, even when contractions of the affected muscles had set in; but he suggested that they should also be stretched with the fingers at regular intervals, or that a wooden ball should be carried in the cheek.

On the whole, however, it would appear that as much (or as little) is to be anticipated from medicinal treatment as from electricity. All recent writers recommend leeches behind the ear, blisters, and mercury or iodide of potassium as the best remedies for facial paralysis during the first two weeks. Erb, in particular, says that the iodide in full doses has appeared to shorten the duration of the disease, even in some "severe" cases.

PARALYSIS OF THE MUSCLES OF THE EYEBALL.—Of the movements of the eyeballs some are direct results of the action of single muscles; while the remainder, for which several muscles are brought into play, are capable of a physiological analysis far more exact than that to which the movements of any other parts of the body can be submitted. Since three distinct cranial nerves are concerned, the study of ocular paralysis has very important bearings upon medical diagnosis. The affections of these nerves cannot be taken separately, because under normal conditions the two eyes are always moved simultaneously, and because the muscles of opposite sides which are associated together are often not the two of the same name, but one of a certain name and the antagonist of its fellow, receiving nerves from different sources. For example, the external rectus of one side, supplied by the sixth nerve, works, not with the *external* rectus, but with the *internal* rectus of the other side, a muscle which receives its branch from the third nerve. Now, one of the most important symptoms of loss of power in the external rectus is a deviation from the natural movements of the internal rectus of the opposite eye, and *vice versâ*, so that the affections of these muscles have to be discussed together.

At the same time it must be borne in mind that two of the ocular muscles receive each the entire distribution of a cranial nerve—the external rectus that of the sixth, the superior oblique that of the fourth. The consequence is that either of these muscles is more likely to be separately paralysed than any single one of the rest, which are all supplied by the third nerve, and that the affections of the former muscles are far the most important from a practical point of view. Moreover, these affections present differences in their symptoms which, *mutatis mutandis*, are typical of those which characterise the paralysis of all the other muscles; so that it is in every way convenient to describe them first.

Paralysis of the sixth nerve.—Each external rectus muscle is associated in its principal movement with the internal rectus of the opposite side. Their combined function is of the most simple kind; they merely carry the eyes to the right or to the left, without any change in the direction of the vertical axes of the globes. Thus, if an external rectus be paralysed, the corresponding eye cannot be moved outwards when the other eye is moved inwards. Let us, for example, suppose that the patient has his *left* sixth nerve

paralysed. The result is that he is unable to look with his left eye at any object to his left. If we hold a candle before him, and move it to his right side, his two eyes follow it until the right one has the edge of its cornea touching the external canthus, and the left has a small part of its cornea buried beneath the caruncle. But if we now carry the candle to his left side the right eye alone follows it; the left remains motionless, and looks straight forwards, or may perhaps perform a slight zigzagging movement to the left under the combined influence of the two obliqui. The further the object is carried to the left the greater is the difference in the directions of the two eyes; and this *primary deviation* or *squint* at once clears up the nature of the case when the paralysis is complete.

If the loss of power is partial the affected eye only lags behind its fellow, and no obvious squint may appear. In such a case one can generally make out the nature of the defect by covering the right or healthy eye; the patient then discovers that he has not got his left eye fixed upon the object, and he accordingly moves that eye further to the left. This correcting movement may be readily detected by a close observer; but what is far more striking is a movement which is simultaneously made by the right eye. For the left external rectus being partially paralysed, any voluntary movement of that muscle requires the exertion of far more effort than that which would have sufficed under normal conditions to produce the same degree of contraction. But whatever amount of nervous energy is put forth, it is at the same time thrown upon the associated muscle—the right internal rectus—which is in possession of its full vigour; and thus the right eye moves two or three times as far as the left one.

This movement of the healthy eye is called *secondary deviation;* and it is of the more importance because it affords a sure means of distinguishing a paralysis of the external rectus from a mere contraction or shortening of one or both of the internal recti, such as exists in cases of ordinary strabismus. When the loss of power is considerable this distinction is indeed made by the fact (above mentioned) that the primary deviation increases as the object looked at is carried further over towards the left side; for if the affection were a mere convergent strabismus the axes of the eyes would remain at exactly the same angle, the one lagging at a fixed distance behind the other, but nevertheless travelling with it, so that such an affection is sometimes called "concomitant." But in slight cases this criterion fails. Its place is then taken by the secondary deviation, the *augmented amplitude* of which is (as we have seen) dependent on the existence of paralysis. In cases of ordinary strabismus the secondary is exactly equal to the primary deviation, since the muscles on both sides possess equal power.

The other symptoms of paralysis of the sixth nerve are subjective sensations experienced by the patient, and of movements to which they lead.

When his eyes are turned in a certain direction he sees double images of the objects at which he looks; and this *diplopia* is not infrequently the first thing which draws his attention to the fact that something is amiss with him. We will assume as before that the *left* external rectus is the muscle paralysed, and we will call the image which is formed upon the retina of the affected (or left) eye "the *false* image;" the one which is formed on the unaffected (or right) eye "the *true* image." It is obvious that double vision occurs only when the eyes are directed to the left, for it is then that they fail to converge properly upon the object. And

a moment's consideration will show that since the left eye has its axis turned inwards (or to the right), the false image must be formed upon the inner side of its retina, and not upon its centre; and, consequently, that it appears to be *outside the true image* or *further to the left.* Both images are upon the same level, and both are upright. By placing a piece of coloured glass before one of the patient's eyes, we can enable him to distinguish very easily which image is formed by that eye, and which by the other; reddish violet is said to be the best colour for this purpose.

It must be borne in mind that diplopia is not necessarily a proof that paralysis of any of the ocular muscles is present. Double images are sometimes formed upon the retina of a single eye; and in other cases they are due to a mere "concomitant strabismus." Making the patient look at the object with each eye separately will exclude the former condition; but the latter can only be dismissed from further consideration if it is found that the two images get wider apart as the object is moved further to the left. One must not assume that diplopia which is of recent origin and which began suddenly cannot be due to concomitant strabismus; for it sometimes happens that a patient whose ocular muscles are imperfectly antagonised is able to keep up the balance between them until he overfatigues his eyes, or until he is weakened by some illness, when he may abruptly begin to squint.

On the other hand, it would be a mistake to suppose that whenever there is a loss of power in the external rectus muscle the patient must necessarily be conscious of diplopia. There is always the possibility that he may not previously have been accustomed to use the two eyes together, or that he may have been in the habit of concentrating his attention upon a single retina, in which case all that he is likely to notice is a blurring of the objects at which he looks, interfering with the distinctness of his vision. One can generally make such a person aware that he really sees double by directing him to fix his eyes upon some bright small object, especially if a coloured glass be held in front of one eye.

Another subjective symptom is that which is known as the "*erroneous projection*" of the visual field. We have seen that a patient who has paralysis of the left external rectus muscle refers the false image of any object to the left of him which he sees with both eyes open, to a position outside its true position, *i. e.* more to the left. The same thing occurs if he is told to look at an object with the right eye closed; except that his judgment is then based upon an appreciation of the degree of effort required to bring his left eye to bear upon it, which effort is augmented in proportion to the failure in the power of the muscle. One consequence is that such a patient feels giddy, and may even stagger, if he attempts to use his left eye alone—a point of some importance, because a careless observer might mistake it for a sign of serious cerebral mischief. Another result of "erroneous projection" may be employed as an aid in the diagnosis of paralysis of the ocular muscles. The patient is told to close the eye supposed to be unaffected, and to strike suddenly at an object placed towards the outer side of the other eye. If the external rectus muscle is paralysed he is sure to miss the object by going to the outer side of it.

Some patients free themselves from the uncomfortable sensations to which this affection gives rise, by keeping the head fixed over towards the paralysed side, so that the images of the objects at which they look may be referred to their right positions.

When paralysis of the external rectus muscle has lasted for a considerable length of time the position of the eyeball often undergoes a further change. It is now drawn inwards by the uncontrolled action of its internal rectus, so that a convergent squint is constantly present, whatever may be the direction in which the patient looks, unless perhaps it be very far to the right. Such a condition was designated by von Graefe the "secondary contraction of the antagonistic muscle;" and he pointed out the curious fact that it is sometimes altogether disproportionate in degree to the loss of power in the muscle originally affected.

Paralysis of the fourth nerve.—The action of the *obliquus superior* is far from being as simple as that of the rectus externus; and its paralysis is proportionately difficult of detection. Each of the two recti, when acting alone, rotates the cornea slightly inwards, beside raising or lowering it; but as one of the obliqui tends to rotate it in an opposite direction, the resultant of their combined action is a straight movement in a vertical plane. The left inferior rectus, by itself, would lower the cornea and carry it towards the right; the left superior obliquus, by itself, would lower it, and carry it round to the left. Acting together, they move it straight downwards. It is further evident that the rotatory action of the two recti upon the (left) cornea must be more apparent when the eyeball has been previously directed outwards to the left; that of the obliqui when it has been previously directed inwards, to the right.

Now let us suppose that the left superior oblique muscle is paralysed. The result must necessarily be that when the patient looks downwards the cornea will be carried to the right by the inferior rectus, which has now no antagonist capable of counteracting its tendency to rotate the globe in that direction. In other words, he will squint to the right and slightly upwards with the affected eye when it is directed upon an object towards his feet. The "secondary deviation" of the sound eye will be downwards and to the left. These symptoms, however, are comparatively little marked, so that the subjective phenomena of diplopia acquire a far greater relative importance in the diagnosis of the paralysis of the fourth than in that of the sixth nerve. The double images are seen chiefly when the patient looks downwards, and their position in regard to one another at once indicates what muscle has lost its power. Thus, firstly, the false image lies *below* the true one; secondly, it is placed to its *left;* and thirdly, it appears to be *tilted* in a particular manner. This last circumstance depends upon the way in which the affected eye is rotated, for since the upper end of an object necessarily has its image formed upon a part of the lower half of the retina outside the normal vertical meridian of the retina, the object itself seems to that eye to be placed obliquely *with its upper end tilted to the right.* Another point noticed by von Graefe is that the false image seems to be on a plane nearer to the eye than the true one; this, he says, depends upon their both being referred to positions upon a horizontal surface spread at the patient's feet, so that the true image, being the upper of the two, is naturally supposed to be the more distant. Moreover, the patient, in order to avoid a sensation of giddiness when he looks with both eyes at objects before him, keeps his head turned downwards and to the right—a position which is very characteristic.

Paralysis of the third nerve.—Since this nerve, unlike the sixth and fourth, is distributed to four of the ocular muscles, the symptoms produced by its

paralysis must of course be different, according as the affection is limited to particular branches or involves all of them alike.

In paralysis of the *internal rectus* the symptoms are the converse of those which belong to paralysis of the abducens. If we take, as before, the muscle of the left side, the "primary deviation" occurs when the eyes are directed on an object towards the right; the affected eye cannot then be moved inwards while the other one is being moved outwards, and a *divergent* squint is produced. The "secondary deviation" of the right eye is towards the right. Double images are perceived by the patient when he looks to the right, and the distance between them increases the further the object is moved in that direction. They are both upon the same level and both upright. They are said to be "crossed;" that is, the false image (which is seen by the left eye) lies to the *right* of the true image (which is seen by the right eye). The "false projection" of the image takes place toward the right; so that the patient, if he aims suddenly at an object with the right eye closed, misses it by going too far to the right. To avoid giddiness the patient keeps his head over to the right.

In paralysis of the left *inferior rectus* most of the symptoms are the converse of those which are produced by paralysis of the superior oblique muscle. As in that affection, the affected eye squints a little upwards when the patient looks downwards, but the rotation of the globe is now to the left. Diplopia occurs when the eyes are directed upon an object below them; the false image is below the true one, lies to its right, and has its upper end tilted to the left.

In paralysis of the left *inferior oblique* the affected eye squints a little downwards when the patient looks upwards; the globe is rotated to the right. The false image lies above and to the left of the true one, and has its upper end tilted to the left.

In paralysis of the left *superior rectus* the affected eye squints a little downwards when the patient looks upwards; the globe is rotated to the left. The false image lies above and to the right of the true one, and has its upper end tilted to the right.

Lastly, if the *whole of the third nerve* on the left side is paralysed, the symptoms are necessarily in great measure identical with those which indicate affections of the muscles severally supplied by its branches. There is complete loss of power to move the eye inwards or upwards. It cannot be moved straight downwards, but it can be lowered slightly if at the same time it is carried a little outwards. In the direction horizontally outwards its play is perfectly free. These last two movements are effected respectively by the muscles supplied by the fourth and sixth nerves, and in the former of these the globe is of course made to revolve on its antero-posterior axis by the uncompensated action of the superior oblique muscle. Indeed, the rotation is so marked under such circumstances—especially when the eye is allowed to move as little outwards as possible—that it affords a striking confirmation of the modern views with regard to the action of the ocular muscles.

The visual range of the affected eye is reduced, according to von Graefe, to about one twelfth of its normal extent; it is limited by a straight horizontal line above, but below by a curved line which sweeps downwards and then outwards.

The direction of the "primary deviation" of the left eye, and that of

the "secondary deviation" of the right eye, necessarily vary according to the position of the object towards which the patient directs his sight; the relations of the false to the true image of course undergo corresponding variations, and so also does the "erroneous projection" of the objects that meet his eye on different sides. The consequence of this is that giddiness is a far more marked symptom when several of the ocular muscles are paralysed than when one alone is affected; and it cannot be obviated by adopting any particular posture for the head, nor, indeed, by any method except that of keeping the affected eye closed. It is only when the patient looks at an object in the extreme left of the visual field that he ceases to squint and sees a single image with the two eyes.

In paralysis of the entire third nerve, beside the affection of the four ocular muscles, there is loss of power in certain other muscles which are also supplied by that nerve. One of these is the levator palpebræ, and the result is that the upper eyelid is dropped, a condition which is termed *ptosis*. The patient is altogether unable to open the eye in the ordinary way; at most he can only slightly separate the lids by wrinkling the forehead—by means of the occipito-frontalis. Ptosis may exist without paralysis of any other muscle; indeed, it is much more common than an isolated affection of any other branch of the third nerve.

Again, the sphincter muscle of the pupil receives filaments from this nerve, and paralysis of them leads to dilatation of the pupil, or (as it is termed) *mydriasis*. Ophthalmic surgeons state that the aperture of the iris never becomes so wide from paralysis as it does under the influence of atropine; but it is often large enough to interfere very much with the accuracy of vision, owing to the formation of "circles of diffusion" upon the retina.

Lastly, the ciliary muscle is also supplied by the third nerve, and hence *paralysis of accommodation* may be one of the symptoms of disease of that nerve. Except in very short-sighted persons, this greatly interferes with distinctness of vision for small print and other near objects. To detect it, one must test the range of accommodation in the usual manner with a convex lens. The head is usually turned obliquely towards the sound side.

Ophthalmoplegia externa.—When all the muscles of the eyeball are paralysed together, there is immobility of the globe with ptosis, but with no squint, and with no double vision for distant objects—unless one eye only is paralysed. This term was used by von Graefe. The paralysis is usually double. More than half the cases are syphilitic and curable. The term *Ophthalmoplegia intima vel interna* has been applied by Hutchinson to paralysis of the iris and ciliary muscle only ('Med.-Chir. Trans.,' 1878, p. 215, and 1879, p. 307).

Ætiology of ocular paralysis.—With regard to the causes of paralysis of the third, fourth, and sixth nerves, our knowledge is at present imperfect. One point of great practical importance is that almost all those cases in which the affection remains limited to a single nerve or to a single branch of the third nerve, terminate sooner or later in recovery. Their anatomy is consequently unknown, but oculists say that they are either syphilitic or "rheumatic" (*i. e.* non-syphilitic).

In 1876 a man died in Guy's Hospital of aortic aneurysm who had about nine months before been in another ward suffering from ptosis of the left eye and pain in the left side of the head. An old meningeal apoplexy was found; the termination of the left internal carotid artery

was dilated, and its coats much thickened; moreover the third nerve on that side was adherent to the side of the artery and stained of a deep brown colour. Sir William Gull used to say of the third nerve that it ran a "dangerous course," on account of its liability to compression in passing between the posterior cerebral and the superior cerebellar arteries, if these vessels should happen to become diseased; and this view certainly accords well with the fact that ptosis is very apt to occur in old people whose arteries are dilated and tortuous.

Of the fourth and sixth nerves it must be remembered that their long and exposed course along the base of the brain renders them very liable to be affected by tubercular or other effusions in that region.

When two or more nerves are simultaneously affected, one suspects the presence of some malignant growth or aneurysm or gumma at the base of the skull. An intra-cranial carotid aneurysm is very likely to compress the sixth nerve for some time before it reaches the rest.

A syphilitic affection of isolated nerves is not necessarily a gumma, for in one case there was ptosis of each eye, while the ocular muscles entirely escaped, and it is difficult to suppose that the corresponding parts of the third nerves were both occupied by a gumma. Probably the lesion is often syphilitic neuritis. Von Graefe is said to have traced to syphilis about one third of all cases of ocular paralysis.

We shall hereafter find that these paralyses may accompany various diseases of the base of the brain, and that they are sometimes early symptoms in locomotor ataxy; but when an organic lesion of the brain or spinal cord is present, one can almost always discover other symptoms, which exclude the supposition of peripheral paralysis.

Prognosis.—Most cases of ptosis or of paralysis of the various ocular muscles recover, except when they are due to aneurysm or malignant growth compressing the affected nerve. But it must be added that recovery is sometimes slow, taking many months; and that it may be imperfect, so that one or more of the affected muscles remain permanently weak.

Treatment.—When the palsy can be traced to syphilis, treatment by mercury is necessary and is usually successful. Iodide of potassium is also useful, and is often given when there is no evidence of syphilis. The application of blisters behind the ear is also believed to be serviceable. Benedikt and Erb have found galvanism useful, a current from six, ten, or fourteen cells being applied for two or three minutes at a time, with the anode on the temple or the back of the neck, and the cathode on the closed eyelids. The improvement is said to be often instantaneously manifested, and Benedikt thinks that if no good is effected within the first fortnight there is no object in continuing this treatment; but according to Erb many cases require to be galvanised for several months before any result is discoverable. Faradic currents also are sometimes useful.

Paralysis of the ninth or hypoglossal nerve is a common symptom of cerebral, pontine, and bulbar paralysis, but as a lesion of the nerve-trunk it is a comparatively rare affection. It is attended with one very remarkable effect, —an extreme degree of wasting on the corresponding side of the tongue. The author has seen two cases of this kind: one was in an old woman, in whom a cancerous nodule (secondary to a cancer of the breast) involved the nerve where it passes through the base of the skull; the other in a boy, who had extensive caries and necrosis of the atlas and neighbouring bones.

In both instances the paralysed half of the tongue was remarkably flaccid and wrinkled; and its tip was curved round towards the affected side. Similar cases have been recorded by Dupuytren, Sir James Paget, and the late Mr Fairlie Clark. In Paget's case ('Clin. Trans.,' vol. iii) the affection was caused by necrosis of a part of the occipital bone, from an injury. Several pieces of dead bone were removed by operation; a few days afterwards the wasted part of the tongue began to grow larger, and within a month it had nearly regained its former size and muscular power. Cases of double hypoglossal paralysis are on record apart from those due to cerebral hæmorrhage and to narcotic poisoning, as in the administration of chloroform. The tongue lies motionless and low between the rami of the mandible, and articulation, deglutition, and even respiration are impeded.

Paralysis of the fifth nerve.—The principal symptom of this affection is anæsthesia of the face. The loss of sensation or the corresponding subjective sensations of numbness and painful tingling may in some cases be traced with great accuracy to the median line of the forehead, nose, and mouth. A circumstance which commonly first attracts the patient's notice is that when he puts a cup to his lips he feels only half of it; it seems to him exactly as though it were broken. The eyelashes and conjunctivæ are perfectly insensible; so also is the nostril, and liquor ammoniæ may be applied to it without causing sneezing; but there is no impairment of the sense of smell, except from diminished secretion of tears and consequent dry state of the mucous membrane. On the other hand, the sense of taste has in several cases been found absent in the anterior portion of the tongue. Three instances of this are given by Romberg in which quinine was used to test the gustatory powers of the patient. It is the same part of the tongue which is deprived of the sense of taste in cases of facial paralysis; and the only possible explanation seems to be that the chorda tympani is a true gustatory nerve, and that in different parts of its course it runs both with the fifth and the seventh nerves, the great petrosal nerve being probably the connecting branch.

Another effect of lesion of the fifth nerve is paralysis of the masticating muscles on the affected side. This only deprives the patient of one movement completely, that in which the lower jaw is carried forwards and towards the healthy side by the external pterygoid muscle. His power of chewing food is much less impaired than might have been expected, but he really masticates only with the muscles of the unaffected side. If he is thin, one can see that the temporal and masseter fail to swell out when the mouth is forcibly closed; even if he is well nourished one can easily feel that they do not harden.

In certain cases of facial anæsthesia the circulation in the affected parts is disordered, or their nutrition is to some extent impaired. Romberg mentions one instance in which the cheek became livid when exposed to cold, in marked contrast with the healthy hue of the opposite side of the face. Sponginess of the gums, ulceration of the mucous membrane of the nose and mouth, and hæmorrhage from their surfaces have been observed. But such changes are rare and comparatively unimportant, whereas there is another affection which is of frequent occurrence, namely, inflammation of the eye, leading to sloughing of the cornea. Physiologists have made this the subject of elaborate investigations on account of its bearing upon the question of trophic nerves. It is now agreed that the inner portion of the trunk

of the fifth nerve contains all those fibres which are specially concerned in the nutrition of the eyeball; but there is still a difference of opinion as to whether the result is due to a mere interruption of their conducting power, or (as Charcot thinks) to some directly irritant influence. Snellen's view that the anæsthesia is its immediate cause, the eye being exposed to mechanical injuries from the loss of the protection afforded by the sensitive nerves, is now generally abandoned; indeed, Charcot cites several instances in which the cornea sloughed as the result of affections of the fifth nerve, unattended with loss of sensation.

We have seen that in affections of the great nerve-trunks of the limbs, when the continuity of their fibres is not completely destroyed, anæsthesia, if present at all, soon passes off. We should therefore expect that a nerve running so protected a course as the fifth would be little liable to have its conducting power for sensory impressions interfered with except by lesions of a serious kind. And this appears to be the case. Romberg, indeed, mentions that a watchman, who had to spend his nights in a hall where the left side of his face was constantly exposed to a draught, experienced violent pains in that part, and subsequently anæsthesia of the second division of the trigeminal nerve; within three weeks, under treatment with iodide of potassium, he recovered. But such instances are extremely rare. The same writer relates two or three other instances in which loss of sensation in the face was due to morbid changes in the Gasserian ganglion, that structure having been found after death to be swollen, indurated, or discoloured. The nature of the change in question seems, however, to be doubtful, and we are not told why a fatal termination occurred.

In the great majority of cases paralysis of the fifth nerve is due to destruction of the trunk or of its ganglion, by caries and necrosis of the bones, syphilitic disease of the pons or meninges, cancerous or sarcomatous growths, or, lastly, aneurysm of the internal carotid artery.

Paralysis of the olfactory nerve.—We will next consider loss of smell, or, as it is termed, *anosmia*. The corresponding affections of the auditory and the optic nerves are too important to be treated adequately in a work on general medicine.

A man may be deprived of the sense of smell in one side of the nose, or in both. When the affection is unilateral he is very likely to remain ignorant of his loss, unless one is particular to test the power of the olfactory nerves separately, carefully closing each nostril in turn. We shall hereafter see that this form of anosmia frequently accompanies hemiplegia. When both nerves are affected the patient is sure to notice the defect His inability to perceive odours is then complete; he is altogether insensible to the most fragrant perfumes and to the strongest stinks. But he retains his susceptibility to pungent vapours, such as those of ammonia and of acetic acid, and snuff is still capable of making him sneeze. The impressions from all these substances are conveyed to the brain by the branches of the fifth nerve which are distributed to the nasal mucous membrane; and it is when that nerve is paralysed that they fail to excite sensations.

But the symptom which chiefly forces itself upon the notice of a patient affected with complete anosmia is not the loss of the sense of smell (as he understands it), but that of a large part of what he supposes to be the sense of taste. He can, indeed, still recognise bitter and sweet, sour and salt; and he can distinguish the rough or smooth character of the food

that he takes into his mouth. But in all other respects his sense of taste appears to be extinguished. He cannot tell one kind of meat from another; apples, onions, and turnips appear the same to him; all kinds of wine seem to have lost their flavour, tasting merely like sour or sweetish water, except that they are more or less rough to the palate. If it were not from habit and prejudice he would probably be altogether indifferent as to the nature of his food. Evidently, therefore, physiologists are right in maintaining that the true gustatory sense is limited to four tastes—sweet and bitter, acid and saline; and that the other perceptions known as tastes belong to the sense of smell.

The pathological significance of anosmia was first fully worked out by Dr Wm. Ogle ('Med.-Chir. Trans.,' 1870). He refers, in the first place, to five cases in which this condition resulted from blows upon the head, the part struck being generally, if not always, the occiput. He believes that in such cases the olfactory nerves are torn across as they pass through the holes in the ethmoid bone. It seems difficult to suppose that all the filaments of both nerves should be simultaneously ruptured; and one would be rather disposed to think that the olfactory bulbs themselves had shared in the bruising of the anterior lobes of the brain, which is so common a result of injuries to the back of the head.

The remaining causes of loss of smell are independent of any affection of the olfactory nerves, but it may be well to enumerate them here. One is, perhaps, an absence of the pigment in the mucous membrane of the upper part of the nose; at least, a case has been recorded in which a negro boy lost the power of smell more or less completely at the same time that his skin became white. Dr Ogle supposes that the nasal pigment also underwent absorption, and he cites some other evidence to show that there is a relation between the presence of this pigment and the olfactory sense. Another cause of anosmia is closure of the passage into the posterior nares by adhesion of the palate to the pharynx; this prevents the patient from drawing air through the nose, and so deprives him of susceptibility to odours, and also to flavours. But there are other conditions in which the one kind of impressions is lost without the other, and which therefore would correspond exactly with the popular conception of an affection of smell, independently of taste. Such cases always depend upon an obstruction to the passage of air upwards to the olfactory region through the anterior nares, while the passage through the posterior nares is open. They generally result from thickening of the Schneiderian membrane by chronic catarrh, so that one part of the lateral wall of the nose is brought into contact with the septum. Dr Ogle mentions the case of a woman who for several years had entirely lost smell from this cause. Some years ago a lady came to the writer who said that for ten months she had lost both smell and taste as the result of a severe cold. Probably what she was really devoid of was the power of appreciating flavours. Some liquor arsenici hydrochloricus was prescribed, and in less than a fortnight she perfectly recovered.

With respect to the loss of the sense of taste, the cases on record, which are certainly of nervous origin, are almost entirely referable to paralysis of the chorda tympani (cf. p. 404). Taste is sometimes affected on one side in hemiplegia. It is unaffected in glosso-pharyngeal paralysis.

PERIPHERAL NEURITIS.—It has long been known that nerve-trunks are liable to inflammation; but we have only lately learnt that many cases of

neuralgia, of trophic changes, and of motor and sensory paralysis are due to this lesion. Leyden explains reflex paralysis generally by ascending peripheral neuritis, and his views have been confirmed by histological evidence. The Wallerian degeneration of a nerve severed from its trophic ganglia is due to parenchymatous neuritis.

In describing neuralgia and peripheral paralysis, we have taken the most uncomplicated examples of both as types: neuralgia of a primary or idiopathic character, not due to pressure or inflammation affecting the nerve; and paralysis such as would be produced by direct injury severing the nerve from its centre. But we have already stated that the less typical kinds of neuralgia, particularly sciatica, are probably pathologically interstitial neuritis; while the trophic disturbance of the skin called shingles and the neuralgia which follows it are due to neuritis of the posterior roots and their ganglia.

Again, the remarkable form of paralysis which sometimes follows Diphtheria is probably due to neuritis; and we shall see that the same pathology most likely belongs to the affections known as Saturnine palsy and Alcoholic paraplegia. Diphtheritic paralysis was treated of in the chapter on the disease of which it is a sequel; lead-palsy will find its place with other atrophic forms of paralysis, and alcoholic paraplegia in the following chapter.

Moreover, progressive neuritis of extensive tracts of peripheral nerves has been clearly ascertained to occur not only as a concomitant or secondary condition, but also as an idiopathic affection involving many nerves, usually in a symmetrical manner, and having its definite course, associated symptoms, and results; in fact, the characters which constitute a "disease" as distinct from a pathological process.

History.—Chomel appears to have first described the clinical features of this affection, which occurred epidemically in Paris in the spring of 1828, and his account was corroborated by Graves, who saw it there in the summer following. The great Irish physician describes it as beginning with pricking and severe pain in the hands and feet, followed by excessive tenderness to the touch. This was succeeded by anæsthesia, and finally by loss of motor power. It thence spread up the arms and legs, but after the patients had lain helpless for weeks they in most cases gradually recovered.

Duménil described a case of the disease in 1864. The clinical symptoms leave little doubt of its nature, and the microscopical examination of the nerves (but not of the cord) by Pouchet confirms that opinion.*

Dr Buzzard described in the 'Clinical Transactions' for 1874 a case of bilateral facial and general paralysis, which recovered under anti-syphilitic treatment, and which he has since regarded as due to multiple peripheral neuritis; but there was no increased excitability of the paralysed muscles to interrupted galvanism, and of course no anatomical proof of the nature of the lesion. There is no mention of the disease as now recognised in Erb's article in 'Ziemssen's Handbuch' (Bd. xii, 2te Auflage, 1876). But in 'Virchow's Archiv' for 1877 (vol. lxix, p. 265), Eichhorst described, under the title "Neuritis acuta progressiva," a remarkable case occurring in a woman of sixty-six, with successive invasion of the nerves of the legs and arms, accompanied by pyrexia. She was suffering from chronic Bright's

* 'Gazette Hebdomadaire,' 1864, p. 203. The same writer contributed a monograph on the subject, with several other cases, to the same Gazette in 1866 (pp. 51—84).

disease. The nerves were examined after death, and were found in a state of neuritis (pl. viii).

Professor Grainger Stewart published three cases of the same affection in the 'Edinburgh Medical Journal' for April, 1881, under the heading "Paralysis of the Hands and Feet from Disease of the Nerves." There is an excellent account of the disease under the title "Progressive Multiple Neuritis" in Dr Ross's treatise (vol. i, p. 354), and Dr Buzzard has published an interesting monograph in his lectures on "Paralysis from Peripheral Neuritis" (1886). He shows the probability that many cases of alcoholic paralysis which recover belong to this pathological group, especially those described by Dr Wilks in his well-known 'Lectures on Diseases of the Nervous System' (p. 272).*

Course and symptoms.—Multiple symmetrical neuritis (called peripheral to exclude affections of the nervous fibres which run in the brain and cord, and of the roots of the vertebral nerves) usually begins somewhat abruptly, and runs a rapidly ingravescent course, though it is less acute than infantile paralysis. Pyrexia is sometimes present. Pain in the course of the nerves affected is quickly followed by more or less complete loss of power in the muscles they supply, and this paresis is accompanied by tingling, numbness, and loss of tactile sensibility, and is frequently followed by trophic disorders of the skin, particularly vesicles and bullæ.

The pain is that of neuralgia, often the peculiar burning pain described as *causalgia* (p. 404). The *anæsthesia* extends over broad patches of skin, sometimes independently of a particular nerve-trunk, and the affected regions are frequently bordered by a zone of hyperæsthesia. The *loss of power* is variable in degree, from the slightest paresis to complete akinesia.

The distribution is symmetrical, and affects the extremities or the face rather than the trunk; and the hands or feet, or both, rather than the proximal parts. The legs are most often affected of all parts of the body, and the extensors of the foot suffer most, so that the patient has a characteristic gait, in which the toe drops and catches the ground.

Faradic contractility is lost, as was noted by Duménil in his first case, and most often, as we should expect, the galvanic contractility is increased, with the other characters of R.D. (p. 400). But Dr Buzzard has found this not to be a constant feature, and it was wanting in a case of peripheral neuritis which recovered under the writer's care.

The *prognosis* is generally good; the most typical cases appear to become rapidly worse, then to remain at a standstill, and then slowly to recover. But in practice our prognosis depends greatly on the clinical features of the case, and especially on its origin.

Diagnosis.—The distinction from neuralgia is not a real one, *i.e.* the pains *are* neuralgic; but anæsthesia (often present to a slight degree in neuralgia) is here nearly absolute, and there is motor paralysis as well. The course and clinical features are different from those of mere neuralgia, and probably the histological condition of the affected nerves is different also. Its symmetry distinguishes it from ordinary hemiplegia and from crossed hemiplegia; while lesions of the pons which affect both sides of the trunk and both sides of the face, without producing rapid death, have rather a theoretical than a practical existence. More often there is difficulty in

* Other cases of paralysis due to alcohol, *e.g.* those recorded by Dr Broadbent ('Med.-Chir. Trans.,' vol. lxvii, 1884), are clearly different in clinical, and probably also in pathological character.

distinguishing multiple neuritis from symmetrical affections of the cord and its membranes, particularly spinal meningitis. Some cases of cervical pachymeningitis, in particular, closely resemble peripheral neuritis. So also do certain central lesions which run an acute course, like Landry's ascending paralysis, and some forms of essential spinal paralysis in adults.

The absence of implication of the bladder and rectum, and of bedsores, distinguish it from destructive transverse lesions of the cord. Hysterical paraplegia does not affect the hands, and is not limited to the feet; while hysterical anæsthesia is unilateral and without akinesia.

The severe pains, along with disturbance of sensation and voluntary movement, are the symptoms which most resemble spinal meningitis. Loss of power in the extensors of the hands ("dropped wrist"), with deep-seated tenderness, resemble the ordinary symptoms of lead palsy, but it is probable that this is itself due to neuritis.

Apart from the characteristic distribution, and the relation to definite nervous tracts, the most distinctive symptom is deep-seated tenderness on pressure, and particularly tenderness of the affected nerve-trunks. The usually favourable course, and the absence of atrophy or rigidity in the affected muscles, are additional helps to diagnosis.

In some cases there are striking exceptions to the usual symptoms. Thus the R.D. may be absent or imperfect; there may be some loss of control over the bladder, as in a case of the writer's above noticed; and there may be, as Leyden has recorded, paraplegic bedsores. Atrophy, commonly slight, may be well marked, or rigidity of the affected muscles may supervene. Probably in these cases the lesion is not confined to the peripheral nerves. Loss of knee-jerk is very common, particularly in alcoholic cases, and with the pains and unsteady gait has led to the diagnosis of tabes. The gait, however, differs from that of locomotor ataxia, as well as from that of cerebellar disease, and is very characteristic of one of the forms of alcoholic paraplegia. If we call the tabid gait "unsteady" or "staggering," and the cerebellar "reeling," we might apply the term "halting" to the dragging of the feet described above.

Histology.—The inflammation affecting the nerve-fibres leads to "breaking up of the axis-cylinder" (Stewart), and "sclerotic atrophy" of the nerves with loss of myelin and thickened perineurium (Leyden).* To the naked eye the affected nerves appear normal, and in the typical cases no secondary changes are found in the nerve-roots or in the cord. By the administration of lead to guinea-pigs, Gombault (quoted by Ross) produced similar changes, not continuous but in segments of the nerves.

Ætiology.—While some of the best-marked cases of peripheral neuritis are apparently idiopathic, others are certainly due to *alcohol*, others are decidedly *gouty*, others are caused by *lead*, and others again are *sequelæ* of enteric fever and other acute diseases, particularly *diphtheria*. The cases which recover cannot, of course, be tested by anatomical investigation; but, judging by clinical features, most cases of lead palsy, certain cases of alcoholic, and certain cases even of *syphilitic* paralysis may be grouped with those described by Chomel and Graves, Eichhorst, Leyden, Stewart, and Buzzard, while diphtheritic paralysis seems always to be of this nature. Some pathologists believe that the enigma offered by the so-called "ascending paralysis of Landry" will be solved by the discovery of its seat in the peripheral nerves.

* See plates 3, 4 and 5 in Mr Bowlby's 'Injuries and Diseases of Nerves.'

At present, however, it is well to leave the best marked of these in their ætiological relations, and still to speak of alcoholic, syphilitic, plumbic, and diphtheritic paralysis.

Of the cases clinically conforming to the character above stated which have fallen under the writer's observation, one was apparently idiopathic, and occurred in an elderly man with great acuteness and severity. He gradually and slowly recovered. Another, of decided alcoholic origin, in a powerful man about thirty, proved fatal after a short course, and the brain and cord were found free from disease. A third, more certainly genuine, occurred soon after an attack of gout, and subsided without local treatment. It was confined to the hands and feet, and showed all the features above described. A fourth was also in a gouty patient.

Treatment.—In gouty, plumbic, and syphilitic cases the appropriate treatment is that which is directed to their respective causes. For patients of intemperate habits, entire abstinence from liquor and assiduous feeding will often succeed against expectation. In "idiopathic" cases no therapeutical measures are at present generally accepted, and it is most rational to treat them, not "on general principles," but according to the "indications of the disease" as successive symptoms demand relief. One plan, however, seems to be almost always beneficial, namely, the application of slowly interrupted galvanic currents.

Neuritis in Beri-beri.—It is worthy of mention, before leaving this subject, that some of the symptoms of a disease endemic in Japan, and known as *Kakké* (*i. e.* weak legs), are remarkably like those of symmetrical peripheral neuritis. It is sometimes epidemic, like the cases described by Chomel, and it is said to be contagious. It is in many cases associated with dropsy, affects young adults especially, and is very apt to recur. In India, including Ceylon, and in Malacca the same malady has long been known under the name of *Beri-beri*. It is also endemic in Brazil. See Mr Wm. Anderson's "Lectures on Japanese Beri-beri," 1879; Morehead ('Br. and For. Med.-Chir. Rev.,' 1855); Fayrer ('Med. Times and Gaz.,' 1880), and Vilette ('Brit. Med. Journ.,' April 23rd, 1887), and a paper in the 'London Medical Record' for January, 1889, p. 13. In Dr Buzzard's second lecture (p. 64), Harada ("Die Japanische Kakké," 1882), and Palm ('Edin. Clin. and Path. Journ.,' September, 1884) are also quoted.

AFFECTIONS OF THE SPINAL CORD

PARAPLEGIA

Παραπληγίη δὲ πάρεσις ἀφῆς καὶ κινήσιος, ἀλλὰ μίρεος, ἢ χειρὸς ἢ σκέλεος.—ARETÆUS.

MENINGEAL AFFECTIONS—*Hæmorrhage—Acute and chronic spinal meningitis.*

OUR knowledge of affections of the spinal cord has of late made great progress; positive diagnosis can now be made of lesions which were unknown to the pathologists of the last generation. Unfortunately, however, the advance has been mainly with respect to diseases comparatively rare. The diagnosis of the more common forms of paraplegia still remains a matter of presumption rather than of certainty, for it is based mainly upon our knowledge that under given circumstances one kind of disease is more frequently met with than another. No doubt the same interpretation of symptoms by probability often guides our diagnosis of diseases of the brain or the abdomen; but compared with the spinal cord there is no other region in which the results of an autopsy are so often unexpected.

Classification.—The arrangement of diseases of the cord is not easy. Very few can be grouped on an ætiological system, since their origin is often most obscure. The pathological processes are comparatively few, and vary

greatly in the symptoms they produce according to their exact seat. Anatomical lesions are peculiarly difficult to determine, from the frequent slowness of their course, from the difficulties of histological examination, and from the rarity of some of the most obscure. Moreover, certain affections of the cord have, so far as the most skilled observers working with modern methods can determine, no anatomy at all. A clinical classification, is therefore, in the present state of our knowledge, most practicable; but the distinction between functional and organic affections, the local distribution of chronic myelitis, and such ætiological facts as bear upon treatment or prognosis must also be regarded.

The plan here adopted will be to describe, first, the most frequent and obvious symptom produced by lesions of the cord, namely, Paraplegia. We will then discuss the peculiarities of paraplegia produced by Myelitis, or by other causes operating *within the cord.*

Next will follow an account of paraplegia when it is the result of direct compression of the cord *from outside.*

We shall next consider a form of paraplegia in which the paralysed muscles become affected with *spasm;* it is separated by other clinical features and by the anatomical lesion which usually accompanies them.

An account of the symptoms produced by affections of the spinal *meninges* will complete the present chapter.

The *atrophic* forms of spinal paralysis—some paraplegic, but others not—are conveniently grouped together, and will form the subject of the next chapter.

Most of these various spinal paralyses are defined by the anatomical lesions to which they may be traced; but there remain two remarkable nervous disorders, which also (while associated with definite changes in the cord) have far more constant and characteristic clinical features than the preceding affections, so that each may be regarded as a natural and connected series of events. These two "diseases"—Tabes and Insular Sclerosis—complete the list of spinal maladies, and will occupy the third and fourth chapters of the present section. The latter, being cerebral as well as spinal in its anatomy, forms a transition to the next section on Diseases of the Brain.

PARAPLEGIA.—This is a form of paralysis possessing two essential features: first, that it affects both sides of the body, generally to an equal extent and in the same degree; and secondly, that it affects all parts, up to a certain level, according to the functions of the several pairs of spinal nerves, ascending from the sacral to the cervical.* It is easy to see why affections of the cord should produce this combination of symptoms. First, the motor tracts belonging to the two halves of the body are so close to one another in the cord that they are generally involved in the same lesion; secondly, since each segment† of the cord contains fibres belonging to all the nerves below, they are all likely to suffer together.

* This is the modern meaning of the word, dating from the last century. Thus, Cullen defines "Paraplegia" as *paralysis dimidii corporis transversim sumpti.* But Hippocrates and Galen applied the word παραπληγία or παραπληξία (for both forms are used) to paralysis of a single limb, and distinguished it from apoplexy as a "side-stroke," *i. e.* a partial palsy only. See the quotation from Aretæus on chronic diseases printed at the top of this chapter (Lib. i, cap. vii). In 1703 paraplegia is defined as *paralysis quæ omnes corporis partes capiti subjectas occupat* (Blancardi, 'Lexicon Medicum').

† A "segment" of the cord is included between any two adjacent horizontal sections.

Although Sir William Gull and other writers have spoken of a "cervical paraplegia," when the arms are paralysed without the legs, the phrase is not strictly accurate. In such cases the affection, if it lies within the cord at all, must be definitely limited to a part only of the segmental area; whereas the morbid changes which cause true paraplegia acknowledge no such limitations. They affect one or more segments in their entire width, sometimes by gradual extension, more often at once, and always at last.

Locality.—As regards their distribution in the length of the cord, the lesions in question vary widely. They may be strictly confined to a single spot, or may extend from the cauda equina to the cervical region, or may transcend the limits of the cord and invade the bulb.

The *upper limit* of a spinal affection is, as a rule, roughly indicated by the extent upwards of the motor paralysis to which it gives rise. Disease of the lumbar enlargement causes paralysis of the lower limbs; disease in the dorsal region causes in addition paralysis of the abdomen and chest, corresponding with the level to which it reaches; disease of the cervical enlargement adds paralysis of the upper limbs; and disease still higher up produces paralysis of the diaphragm and of the cervical muscles in addition to that of all the parts below, and so soon as developed is of necessity fatal.

The *lower limit* of a spinal affection is more difficult to fix, since a complete transverse lesion of the cord will, however short, paralyse all the fibres below. Inasmuch, however, as the cord is a collection of centres as well as of conducting tracts, we can to some extent define the lower limits by a study of its reflex functions (*infra*, p. 433).

In some cases the feet and legs become powerless before the thighs and the hips. This is generally supposed to mean that the lesion is at first confined to the extreme lower end of the lumbar enlargement; but, since Woroschiloff found that in the lateral columns of the lumbar cord of the rabbit the motor paths for the distal parts of the lower limbs lie outside those for the proximal parts, it has been thought that the symptom in question may sometimes be due to gradual extension of disease from the surface inwards.

When paralysis attacks the upper extremities in detail, as the result of disease spreading upwards through the cord, the muscles of the hands are as a rule affected before those of the elbow and the shoulder. The fact

It takes the *whole thickness* of the cord, and a single pair of nerves. We thus recognise eight cervical, twelve dorsal, and a number of lumbo-sacral segments, although the last are too closely packed together for us to be able always to distinguish their several lesions.

It must be carefully borne in mind that while each segment generally resembles the rest, there are important differences between them: first, in the total size and shape; secondly, in the proportion of grey to white matter, and the size of the anterior cornua; thirdly, in the development of the several "tracts" of the cord.

Thus, as we pass downwards, the crossed pyramidal tract becomes smaller and more superficial; the direct cerebellar and direct pyramidal tracts gradually disappear; the postero-median column of Goll becomes smaller and deeper. The anterior cornua are very large in the cervical and lumbar enlargements, very small in the dorsal region; while the important group of cells known as Clarke's vesicular column is well represented in the dorsal (especially the lower dorsal) region, and is almost absent in the cervical and lumbar.

It must be remembered that the lumbar or lumbo-sacral enlargement is so named from its giving origin to the nerves of the lumbar and sacral plexuses, but that it does not, like the cervical and dorsal regions, correspond to the vertebræ of the same name. The cord ends, in the adult, at the first lumbar vertebra, and from the mid-cervical region the nerves pass downwards to their foramina of exit from the vertebral canal, with increasing obliquity, until they are collected together to form the cauda equina.

that the nerves to the ulnar side of the hand come chiefly from the lowest part of the brachial plexus would lead one to expect that the inner fingers would suffer earlier than the outer fingers or the thumb.*

Sensory symptoms.—When any segment of the cord is completely destroyed, there is of course an absolute loss of *sensation*, as well as of motion, in all parts of the body below the lesion. And when a total disorganisation spreads upwards through its substance, the gradual progress of the disease from day to day can be determined from the extension of the anæsthesia with far greater accuracy than is possible from that of the motor paralysis alone. But in the great majority of cases, parts affected with paraplegia either retain perfect sensation, or have that function but little impaired.

This preponderance of loss of motion over loss of sensation is not only met with in all diffused spinal affections, but belongs to them in common with diseases of the peripheral nerves and of the brain itself. And the true explanation is, no doubt, that which was given when the diseases of the nerves were under consideration; namely, that sensory impulses are transmitted far more easily than motor ones, so that there is no anæsthesia unless the conducting fibres are completely disorganised.

Beside the abolition of the sense of touch in completely paralysed limbs, there is loss of the sense of temperature and of the muscular sense and absence of pain (*analgesia*). Many paraplegic patients who retain the sense of touch complain of "pins and needles," "pricking" or "tingling" in the toes or in paralysed parts, "creeping" or "crawling" (*formicatio*), or subjective sense of heat or of cold—perverted sensations which are conveniently called *paræsthesiæ*.

Physiological explanation of symptoms.—There are certain affections which are strictly limited to particular tracts of the grey or of the white matter; but we shall find that none of these are characterised by purely motor or sensory paralysis (*akinesia* or *anæsthesia* respectively) of the parts below. The lesions which are diffused over the whole segmental area of the cord commonly cause more loss of motion than of sensation.

All physiologists are agreed that volitional motor impulses pass mainly along the crossed pyramidal tracts of the antero-lateral columns. With regard to the paths for sensory impulses, there still is doubt. One opinion, maintained by Brown-Séquard, was that they are all situated in the grey matter. Another, which was first taught by Schiff, is that tactile sensations are transmitted through the posterior columns, but sensations of pain through the grey matter. A third and better supported hypothesis places the chief sensory tracts in the deeper part of the lateral columns of the opposite side.

We shall find that a central tubercular nodule is occasionally the cause of paraplegia. But anæsthesia does not precede motor paralysis in cases of this kind, as on Brown-Séquard's theory it should. Again, if Schiff's doctrine were correct, such an affection should cause analgesia, tactile sensation being retained; but as yet nothing of the kind seems to have been noticed. It may be replied that a central tubercle of the cord does not completely disorganise the grey matter before it presses

* According to Erb ('Ziemssen's Handbuch,' xi, 2, p. 62) paralysis of all four limbs, and of the trunk muscles generally, sometimes occurs without any interference with the respiratory movements, as the result of an exceptional limitation of disease to a part of the segmental area of the cord in the cervical region, leaving the lateral columns intact. Strictly speaking, such an affection is not paraplegic in the sense defined above.

on the white columns; but this is the very difficulty: the diseases which cause paraplegia are not so localised as to admit of the application of rules deduced from experiment. One physiological result, however, is of great clinical importance, namely, that the sensory fibres do not cross at the decussation of the pyramids in the bulb, but pass over to the opposite side, at once or gradually, at no great distance from the posterior roots.

Partial paraplegia.—Hitherto we have referred to complete motor paraplegia, a condition in which the affected muscles are altogether incapable of being influenced by the will; but in a large number of cases the paralysis is incomplete. Every degree of loss of power may be noticed. One patient can just move his toes, another can flex the knees so long as they lie horizontally on the bed; a third can draw the thighs up to the abdomen; a fourth can stand for an instant and then falls down; a fifth can walk a few paces, and so on, up to a condition in which all that can be detected on the most careful examination is a slight uncertainty of step, with a tendency to catch one of the feet against any slight obstacle. When "paresis" (as partial mator paralysis is called) is more marked the gait is peculiar, and it is well worthy of study because it contrasts with that which is observed in some other spinal affections that will be discussed further on. Erb describes it in the following terms:—"The foot hangs down in walking, the toes are dragged, the sole is brought to the ground clumsily, and for the most part upon its outer edge; the knee is too much raised or carried forwards without being bent; there is generally a kind of stiffness about the legs. The patient uses one or even two sticks, or he is held up by crutches or by the arms of other persons; he totters but slightly, and stands quietly and steadily. When left unsupported he sinks down upon the ground. The gait of course varies somewhat according to the number of muscles which are paralysed. When only those below the knees are affected it is waddling and very peculiar."

In those cases of partial paraplegia in which sensation is also impaired the patient feels when he stands upon his feet as though they were wrapped in wadding or covered with thick woollen stockings; or a hard floor may seem to him like a thick felt carpet. In such cases he requires the guidance of vision to enable him to stand firmly or to walk evenly. When a patient who has his feet close together totters or falls as soon as he is made to close his eyes, he is often assumed to be suffering from a special disease of the cord—sclerosis of the posterior columns (tabes or locomotor ataxy). But although the symptom in question is present in that disease, it is yet by no means peculiar to it, being met with whenever there is an imperfect transmission of those sensory impulses from the feet by which the equilibrium of the body in the erect posture is normally maintained.

Reflex symptoms.—The *lower limit* of a lesion of the cord cannot be determined with any great accuracy. We have seen that disease in the cervical region renders the legs as well as the arms paraplegic, and this equally whether the affection is confined to a small part of the length of the cord or involves the whole of it down to the cauda equina. An easy experiment, however, enables us in many cases to say that at least some of the lower segments retain their functions, although their connection with the brain is cut off. We have but to see whether *reflex movements* can be excited in the legs by impressions upon the cutaneous nerves. If this experiment succeeds, it proves that the lumbar enlargement is still undestroyed. On the other

hand, its failure is not to be taken as conclusive evidence that the disease extends throughout the whole of the lower part of the cord. On the contrary, it often happens in cases of very limited lesions that reflex movements can only now and then be elicited. For example, surgeons find, when there is fracture with displacement of the upper dorsal or cervical vertebræ, that for a few days after the accident there is an entire absence of reflex excitability in the cord; it seems to have been in some way deprived of its functions by the shock.* So, also, we shall hereafter learn that the reflex movements are generally less readily obtained when disease has begun in the interior of the cord than when it is merely compressed from without; the reason being that in the former case an "inhibitory" influence is transmitted downwards upon the lower centres. Even when these retain or have regained their susceptibility, it may sometimes be easily exhausted for a while by repeated stimulation. In a well-known paper, read before the Royal Medical and Chirurgical Society in 1839, Dr William Budd mentions the case of a young lady in whom the slightest disturbance of the bedclothes caused very energetic contractions of the right leg, which was paralysed; but there was a successive diminution in the vigour of the spasms on each renewal of the stimulus. The impressions that produce reflex movements are sometimes felt, and in the case of this young lady the movements themselves were attended with pain like that of cramp. On the other hand, Dr Budd relates an instance in which all the limbs were paralysed by an injury to the cord in the cervical region, but in which convulsions in the arms were excited by pulling the hair of the head or by tickling the chin; the efferent impulses must then have traversed the seat of lesion, through which no volitional efforts could be made to pass. As a rule, however, cases in which all communication with the brain is absolutely cut off are those in which the reflex activity of the cord is most marked; the patient then has no consciousness either of the application of the stimulus or of its effect, unless he sees the jerking of his legs. It seems probable that the susceptibility of the lower spinal centres is often directly augmented by an irritant influence transmitted downwards from the diseased part; for the administration of strychnia excites spasms in paralysed limbs much earlier than in those which remain obedient to the will. Sensitive impressions upon the skin of the soles of the feet seem to set up reflex movements in the legs much more easily than simular stimuli applied to any other part of the cutaneous surface; lightly touching the hollow of the foot with a feather often throws the whole limb into spasm. Again, a hot metal plate produces much more marked effects than one at an ordinary temperature, even when the transmission of sensory impressions is so imperfect that the patient cannot tell the difference. But the most violent convulsions of all are those which are sometimes excited by micturition and by defæcation. One of Dr Budd's patients was obliged, whenever he was placed upon the night-stool, to have his feet inserted into two large loops of saddlers' webbing which were nailed to the floor, to have two larger loops adjusted over his knees, and to hold down his thighs; otherwise he was liable to be thrown forwards upon the ground.

Reflex movements are more or less co-ordinated. There seems no reason to suppose that muscles are individually represented in the spinal centres. And whatever may be the machinery in the brain by which the

* See the instructive remarks of Prof. Goltz on this subject in his 'Verrichtungen des Grosshirns,' S. 78—81.

several groups of muscles are harmonised and co-ordinated in their actions so as to produce definite movements, it is certain that cross-connections exist within the cord by means of which a similar result can be brought about. We do not see such marked purposive reflex movements in a paraplegic patient as are observed in decapitated frogs; but a near approach to them was seen in a case of Dr McDonnell's, recorded in the 'Dublin Quart. Journ.' for 1871. The patient was paralysed in all four limbs; when a catheter was passed into his bladder his left arm would "wriggle up and down, and the hand come fluttering over the genital organs, although he was absolutely unconscious of the operation, and even when his eyes were shut." Another curious case is related by Virchow. It is that of a man who was paraplegic, and who generally lay in bed with his lower limbs rigidly flexed. When he wanted to stand upright he would pinch the right thigh sharply, or give it a smart blow on its outer surface; this threw both the legs into a position of extension; still the gastrocnemii remained contracted, and before he could put his foot to the ground he had to bring down the heels with both hands ('Gesammelte Abhandlungen,' p. 684).

A curious illustration of the way in which one set of reflex actions may be made to conteract another set is afforded by a case of Dr Budd's. The patient was recovering from paraplegia and could walk a few steps, until the contact of the soles of his feet with the ground would make his knees bend beneath him; this he was able to overcome by rubbing the surface of his belly, when the legs were extended with a jerk.

As a rule, when reflex movements are excited by impressions upon the cutaneous surface, they remain confined to the limb on the same side. Leyden says that they do not spread to the opposite limb except when the lesion is in the bulb, but many instances to the contrary may be found. The movements generally consist in a rapid series of intermittent (*clonic*) spasms; but sometimes the contraction is continuous (or *tonic*) in character.

Beside the well-known reflex movements called *plantar* and *cremasteric*, there are several others of diagnostic value as localising symptoms in cases of paraplegia.

(1) Some are obtained by touching, pinching, or stroking the skin so as to produce contraction of the underlying muscles. The following are the most important of these superficial reflexes:—The *abdominal*, when the external oblique muscle contracts; the *epigastric*, when tickling the skin over the fourth to the sixth ribs produces contraction of the upper segment of the rectus; the *gluteal*, when irritation of the skin of the buttock leads to dimpling over the insertion of the glutæus maximus into the fascia lata; and the *scapular*, a slight movement of the teres major in the fold of the axilla when the skin between the shoulders is pinched. All these are most easily produced in children; and others may be discovered at an early age, as the *palmar* reflex or closure of the fingers produced by gently touching the palm of a sleeping infant. In elderly people several are absent, and all are less readily elicited.

As criteria of the seat of a spinal lesion:—the *plantar* reflex corresponds to the sciatic nerve and lower part of the lumbar enlargement of the cord, situated in the adult opposite the last dorsal spinous process; the *gluteal* reflex corresponds to the fourth and fifth posterior lumbar branches, the lumbar enlargement, and inferior gluteal nerve; the *cremasteric* to the first and second anterior lumbar branches; the *abdominal* to the lower three or four intercostal nerves and dorsal cord; the *epigastric* to the middle intercostals

(fifth to seventh), and the upper dorsal cord; and the *scapular* to the upper bundle of the brachial plexus, and the cervical enlargement of the cord.*

(2) There are what may be termed Visceral Reflexes:—*vesical*, when the bladder is caused to contract by irritation of the urethral orifice, of which the incontinence of urine in children, by reason of a long prepuce, is an example; *penile*, when erection is produced by the passage of a catheter or by the slightest contact, a condition sometimes seen in cases of partial paraplegia, short of that which produces priapism; *rectal*, as when contraction of the bowel follows the introduction of a suppository; lastly, the familiar reflex actions of *vomiting* from tickling the fauces, *sneezing* from a draught of cold air or a brilliant light, *blinking* from touching the cornea, and contraction of the *pupil* to light and during accommodation for a near object.

The movement of the ribs in *respiration* enables us to judge of the integrity of the connection of the intercostal nerves with the brain, or of the point where it is severed by transverse lesion of the cord. The act of *swallowing* depends on the centre situated in the bulb, and that of *contraction of the iris* on the centrum ciliospinale in the same region.

(3) A closely connected set of phenomena have been called *deep reflexes*, but it is still doubtful whether they are due to reflex or direct stimulation of the muscles involved.† Dr Gowers suggests "*myotatic* movements" as a safe synonym.

The most important was first described in 1875, by Westphal and Erb independently; it was called by the latter the "patellar tendon-reflex," by the former the "knee-phenomenon." The best English name is *knee-jerk*, and it has long been known to schoolboys. A smart tap is given with the side of the hand upon the tendon of the great quadriceps extensor muscle of the leg, above or below the patella, while the knee is crossed over the opposite thigh; and the foot is jerked upwards. A similar *elbow-jerk* may be obtained in most healthy persons by striking the stretched tendon of insertion of the triceps extensor brachii.

The absence of the knee-jerk is usually, perhaps always, a morbid sign; but different persons vary much in the readiness with which it is procured. It is exaggerated in paraplegia, but, contrary to what we should expect, is as a rule diminished in the paralysed leg of hemiplegia. In morbidly excitable conditions the jerk may sometimes be obtained by stretching the ligamentum patellæ and striking the subcutaneous surface of the tibia; or, by stretching the tendo Achillis and tapping the tibialis anticus and extensors of the toes, an extension of the foot may be obtained (Gowers' front-tap contraction).

The so-called deep reflexes do not always increase or diminish in correspondence with the superficial reflexes.

Ankle-clonus is the name given to the clonic contractions produced in some patients by forcibly bending up the foot so as to make the tendo Achillis tense. It was first described by Charcot, and is included by Erb and Westphal among tendon-reflexes. It usually goes with exaggerated knee-jerk, and is probably always a morbid phenomenon. But a somewhat

* See Dr Gowers' useful diagram ('Diagnosis of Disease of the Spinal Cord,' p. 58).

† See papers by Tschirjew ('Arch. f. Psychiatrie,' 1877, and Du Bois's 'Arch.,' 1879), Gowers ('Lancet,' i, p. 156, 1876), Waller ('Brain,' July, 1880), and De Watteville ('Brit. Med. Journ.,' 1882, p. 736); also by Bowditch and Warren ('Journ. of Physiology,' vol. xi, 1890).

different kind of clonic spasm of the gastrocnemius can be obtained in most healthy persons by bending the knee and ankle with the ball of the foot resting on the ground, and moving the knee rapidly up and down.

The paralysed muscles.—The condition of the centres in the cord has a direct influence on the nutrition of the paralysed muscles.

We have seen that when disease destroys the entire substance of the cord up to a certain level no reflex movements of any kind can be obtained in the limbs below. Under these circumstances the muscles rapidly lose their electrical contractility, and they undergo marked *atrophy*. Before complete loss of susceptibility to galvanic currents supervenes, there is generally a period in which the reaction of degeneration is present (cf. p. 400). On the other hand, when paraplegia is due to a lesion limited to one of the upper segments of the cord, so that reflex movements persist in the paralysed limbs, the muscles, as a rule, retain their normal electrical reactions, and they remain tolerably well nourished for months and years, or show merely such slight flaccidity and wasting as may fairly be attributed to disuse. They are still in connection with their trophic centres in the anterior cornua.

Again, paraplegic muscles may become *rigid*, so that the legs are either forcibly extended, or drawn up in a state of flexion. Cases of this kind will be separately described hereafter, under the name of "spastic paraplegia." The knee-jerk is almost always exaggerated and clonus is present.

The bladder in paraplegia.—Unstriated as well as striated muscles can be excited to reflex contractions. Erb mentions a curious case of paraplegia, in which a fluid fæcal evacuation was passed whenever a large bedsore was dressed. In other instances micturition was directly produced by pressure over the bladder, or by the introduction of the finger into the rectum. It does not follow that impulses were reflected to the vesical muscular fibres after being conveyed to the cord by cutaneous nerves, for the slightest compression of any part of the distended bladder appears to be a sufficient direct stimulus to its muscular fibres. Indeed, in the apparently volitional act of micturition in health the influence of the will is really limited to relaxing the sphincter and throwing the abdominal muscles into contraction, so as to press upon the bladder and set in action its reflex machinery. The experiments of Goltz upon young dogs ('Pflüger's Archiv,' 1874) have shown that in these animals the bladder is capable of emptying itself at regular intervals, and in a perfectly normal manner, after the cord has been completely cut across by a sharp knife.

Thus physiology would lead us to expect that micturition would take place naturally in those cases of paraplegia in which the lesion is limited to the upper part of the cord. In practice, however, it is found that retention of urine almost invariably occurs, even when reflex movements can be easily excited in the lower limbs, proving that the lumbar centres are intact. The explanation doubtless is that an inhibitory influence is transmitted downwards upon those centres from the diseased part above. Goltz, in fact, states that in some of his experiments it was not until several days after the operation of section of the cord that the animal was able to micturate properly; and he suggests that in cases of injury to the spine in man the bladder would after a time be found to have regained its functions if catheterism were not continued as a matter of routine. However this may be, it is certain that the theoretical accuracy of Goltz's views with regard to micturition is established by some exceptional cases of paraplegia, in which the urine is passed quite naturally. It is remarkable how many of the patients

whose cases are related by Dr Budd in his well-known paper were able to micturate, though not always in a perfectly normal manner. In the case already cited as presenting such violent convulsive movements of the legs (p. 432) the urine at first began to flow in interrupted jets, but as the spasms grew more feeble its stream became continuous. Another patient, at a certain period in his illness, emptied his bladder involuntarily and with a sort of jerk about every two hours. In a third case, one of fracture of the spine, in which there was at first retention, the power of voiding urine naturally was regained on the fifth day, whereas no volitional movements in the legs occurred until the ninth day. So, again, one of the cases related by Ollivier, in his classical work,* is that of a man who had complete paralysis of his lower limbs as the result of caries of some of the higher dorsal vertebræ, but in whom the bladder performed its functions normally.

It is an interesting question whether the converse can occur—that is, whether the lumbar centre for micturition is ever the only part of the cord diseased, so that while the bladder is paralysed the lower limbs nevertheless retain the power of movement. It seems probable that such a condition exists, though it is rare.†

In some instances in which the power of micturition is partially impaired one can distinguish paralysis of the *sphincter* from that of the *detrusor urinæ*, by which expulsion of the urine is mainly effected. It might have been supposed that in the former case there would be complete incontinence, the fluid dribbling away incessantly. But physiologists have found that even after destruction of the lumbar cord the neck of the bladder can withstand a pressure of six inches of water—as compared with one of twenty inches when the cord is intact; and this result is entirely confirmed by some observations of Hutchinson ('Brit. Med. Journ.,' 1877) upon persons who have the remains of a shrunken spina bifida, involving the fourth pair of sacral nerves, so that the sphincters of the bladder and rectum alone are permanently paralysed. In such cases he finds that the bladder may be able to hold a large quantity of urine, but if once its reflex contractions are excited the will is, of course, powerless to restrain them, and therefore there is a constant risk of accidents. So in many cases of partial paraplegia the patient says that as soon as he feels the inclination to micturate he is obliged to indulge it, so that the urine is apt to escape before he can get to the chamber vessel. But when the detrusor is paralysed the complaint is that he has to strain for a minute or two before he can pass any water, that it comes away slowly in a feeble stream, and trickles for some little time after voluntary effort has ceased.

On the other hand, when the "micturition centre" in the lower part of the cord is wholly deprived of its functions by disease or injury, the sphincter and the detrusor of the bladder are of course paralysed together. The

* 'Traité de la Moelle Épinière et de ses Maladies,' par C. P. Ollivier: 1st ed., 1821; 3rd, 1837, with plates.

† I have notes of more than one case in which retention of urine has preceded all other indications of the onset of paraplegia by an interval of a few days, but I do not remember any instance in which it has continued to be the sole or even the main symptom of a spinal affection. Some years ago I saw a gentleman who was one of the sufferers in the Thorpe railway collision, and whose chief complaint was that he could pass his water only in a very feeble stream; he said that "it flowed from him like oil," and it quickly became ammoniacal and very fœtid. He had pain and tenderness in the back, but the only sign of any loss of power in the lower limbs was that in walking he sometimes seemed to totter, especially if his foot caught against any slight obstacle; he also had "twitchings" in the legs three or four times a day. He was not long in getting perfectly well —C. H. F.

result is that the organ becomes distended, and that the excess of urine beyond what it can hold dribbles away through the urethra. The Germans call this condition "ischuria paradoxa." It has often been mistaken for incontinence; an unskilled nurse is very apt to suppose that there can be no retention of urine in the case of a patient who is constantly wet, and her statements may mislead a careless practitioner; but one can always avoid such an error by passing one's hand over the lower part of the abdomen. In incontinence of urine from paralysis of the sphincter alone, the bladder keeps firmly contracted and almost perfectly empty, while its walls become greatly hypertrophied. It seems to be still doubtful whether this kind of incontinence always depends upon an exaltation of the reflex activity of an intact lumbar centre, or whether it may occur after that part of the cord has been destroyed, as the result of contractions of the detrusor, which may either be spontaneous or dependent upon minute intrinsic ganglia of the bladder.*

The urine in paraplegia.—We have still to consider certain changes in the urine, and in the organs that secrete and expel it, which are of the highest clinical importance. Sir Benjamin Brodie many years ago pointed out (in the 'Med.-Chir. Trans.' for 1836) that in cases of injury to the spine the urine is often voided alkaline, ammoniacal, and turbid, even as early as the second or third day; it is well known that in most cases of paraplegia due to disease of the cord the same thing occurs, but generally not until a longer time has elapsed. Its explanation is still a matter of doubt. Charcot believes that it is in some way due to a direct action of the nervous centres upon the urinary organs. Other writers regard it as a result of decomposition of the urine, after secretion, while it is stagnant in the cavity of the bladder. This does not mean that only those patients who have complete retention pass urine which is alkaline and fœtid, for there can be no doubt that a very slight impairment of the power of the bladder may prevent it from emptying itself completely. But the difficulty is to understand how the change in the urine is brought about, apart from the access of air and of the *micrococcus ureæ*. Traube, of Berlin, made the important suggestion that an ill-cleansed catheter might start decomposition; and one should always use antiseptic precautions before introducing an instrument into the bladder. But in more than one case where the catheter was never used the urine has become putrid.†

Moreover, although we may admit that decomposed urine is capable of exciting inflammation of the bladder and of the urinary passages, it does not appear that there is always such an interval of time as would be required for the production of this effect. Charcot cites cases in which the urine contained blood as early as the third and the fourth day respectively, and the presence of blood is generally followed in a very few days by that of pus, or of the gelatinous substance which is formed out of pus in a strongly alkaline liquid. It is therefore possible that cystitis is in some cases the primary, and ammoniacal urine the secondary event.

On *post-mortem* examination, in cases of this kind, one finds the most intense cystitis and suppurative nephritis; and, indeed, these affections have most commonly been the direct cause of death. The mucous membrane of

* See a paper by Dr Francis Darwin, 'Quart. Journ. of Micr. Sci.,' 1874, p. 109.

† Dr Goodhart, in the 'Guy's Hosp. Rep.' for 1874, suggests that an almost stagnant column of urine filling the urethra might suffice to enable the *micrococcus ureæ* or other putrefactive microbes to pass into the bladder.

the bladder is ecchymosed or swollen, infiltrated with inflammatory products, lined with a "diphtheritic" layer or with a granular deposit of phosphates, or actually sloughing. Its muscular wall is often free from hypertrophy, but sometimes it is greatly thickened; in one case at Guy's Hospital it measured at least a twelfth of an inch across, although the disease had lasted only four or five weeks. The kidneys are enlarged, intensely congested, and full of suppurating points and streaks; in other words, they present all the characters of an "ascending inflammation."

Rectum and genitalia.—Some other symptoms connected with the pelvic organs may be conveniently mentioned here. One of them belongs to the *rectum*. Although the peristaltic movements of the intestine are not directly dependent on the spinal cord, the sphincter ani is under the control of a lumbar centre. Consequently, as a rule, it becomes paralysed with the bladder; and incontinence of the fæces generally accompanies or follows retention of urine.

Another symptom concerns the male genitalia. *Priapism* is of frequent occurrence in paraplegia. It is one of the results of the reflex activity of the lower part of the cord. Sometimes it is constant; sometimes it only appears when the bladder is distended, or when a catheter is passed. Goltz, in his experiments on paraplegic dogs, traced out carefully the various ways in which this symptom could be induced by irritating the skin of the abdomen, or of the thighs, or the sheath of the penis, and he found that he could easily inhibit it by simultaneously irritating the sciatic nerve, or by pinching the hind foot. The last observation—showing that the centre for erection is very sensitive to disturbing influences—may serve to explain the fact that a temporary loss of sexual power is not infrequently observed in persons who have been in a railway accident, but in whom there are no other symptoms of serious spinal injury.

When the lumbar enlargement of the cord is destroyed, priapism is of course altogether absent.

As regards the female organs, it is worthy of mention that *parturition* may take place naturally in a woman suffering from paraplegia, provided that the lumbar centres remain intact.

Bedsores.—A circumstance which points towards the conclusion advocated by Charcot—that morbid changes in the bladder and urine are at least sometimes directly dependent upon an influence transmitted from the nervous centres—is that their development is commonly coincident with that of gangrene of the skin over the sacrum and the gluteal regions adjacent. An "acute bedsore," in fact, sometimes begins to form as early as the fourth day. Many instances of this kind are quoted by Charcot; but none is more striking than a case recorded by Sir William Gull, of a man who on November 22nd, 1856, was working in the docks, when he felt a sudden pain in the back after lifting some deals; he became paraplegic on the 24th, and on the 26th was admitted into the hospital with a small bedsore already present. It is clear that in such cases the affection cannot be regarded as a mere result of pressure upon the skin, nor of the irritant action of excreta passed without the patient's knowledge; but there seems to be no doubt that each of these conditions is concerned in the production of the more chronic bedsores which do not appear until after the lapse of weeks or months. An acute bedsore may sometimes be made to heal, if carefully attended to; this occurred in the case just quoted, but afterwards another one formed at the same spot, and it rapidly increased in size, so that, when the disease

ended fatally, six weeks from its commencement, the whole of the sacrum was exposed. Indeed, a bedsore may destroy life, either by exhaustion, or by pyæmia, or by extension of putrid inflammation into the spinal canal.

The four symptoms last described—retention of urine, incontinence of fæces, priapism, and acute bedsores—are apt to go together, and may be conveniently grouped together as the "pelvic symptoms" of paraplegia.

The morbid conditions that give rise to paraplegia fall naturally into two groups. The first includes all those affections which have their seat *within the cord itself*. The second is made up of those in which the primary lesion is *outside the cord*, and subjects it to *slow compression*. The division is not exhaustive; but it is one of practical importance, because in the second group there is a characteristic chain of symptoms dependent upon interference with the nerve-roots at the level of the lesion.

MYELITIS.—Among the affections beginning within the spinal cord itself and capable of causing paraplegia, the most important and by far the most frequent is one which is now believed by most pathologists to be a more or less diffused inflammation of its substance, and which they therefore term *myelitis*. This, again, presents many varieties in its symptoms and course, and in the morbid appearances to which it gives rise; but in the main they may be arranged into two classes, according as their progress is *acute* or *chronic*.

*Acute diffuse myelitis.**—It has long been known that in many cases of paraplegia the cord is found after death to be more or less extensively softened; and from the time of Ollivier the opinion has been maintained by most pathologists that the morbid process in question is of an inflammatory nature. There are, indeed, obvious objections to such a view. It involves the admission that a remarkable contrast exists between softening of the cord and a similar change in the brain. The latter (as we shall hereafter find) is most frequently the result of a deficient supply of arterial blood to the affected part of the cerebral substance; and when it is inflammatory it is almost always traceable to some definite local irritation. The former, on the other hand, can very seldom be shown to be secondary to interruption of the blood supply, and its chief causes are supposed to be functional exhaustion or exposure to cold. A more serious difficulty is that the histological appearances correspond only partially with those which are seen in inflamed tissues generally, and that even the naked-eye changes are not altogether such as are met with in the spinal cords of animals when inflammation has been artificially set up. Leyden, for example, induced myelitis in dogs by injecting solution of arsenic, and obtained greenish patches of purulent infiltration, surrounded by vascular zones; but, in human pathology, the presence of anything that can be recognised as pus in the spinal cord is quite exceptional. On these and other grounds Dr Bastian regards most cases called acute myelitis not as strictly inflammatory, but as a process of softening secondary to thrombosis or other vascular changes.

The late Dr Moxon, in his Croonian Lectures before the College of Physicians, drew attention to the scanty vascular supply of the lower part of the cord owing to the fewness, small calibre, and prolonged course of its

* *Synonyms.*—Acute softening of the cord. Red and yellow softening. Myelomalacia.

arteries, and to its not having with the brain an internal set of vessels in addition to those of its pia mater; and justly argued that this anatomical condition may explain some of the peculiarities of anæmia, thrombosis, and inflammation as they affect the spinal cord.

Anatomy.—The colour of the spinal cord when softened is very variable. Sometimes its tissue is pink or bright *red* from vascular injection; sometimes it is mottled with small ecchymoses; or it may be so saturated with extravasated blood (hæmato-myelitis) that the case seems to be one of spinal hæmorrhage, an affection, however, of which the occurrence is denied by many modern pathologists. Probably all these appearances are confined to an early stage of the inflammatory process; for afterwards the blood undergoes changes which give to the diseased parts a tawny *yellow* tint, due to the presence of hæmatoidin crystals and of fatty degeneration in the form of "compound granule-corpuscles." If no hæmorrhage has occurred the softened spot as a rule is *white*;* or in rare cases of a *greenish* tint from suppuration.

The fact that one part of the spinal cord is softer than the rest, or that it looks diffluent when cut across, is not of itself a proof that disease is present. The softening may result from bruising with the bone forceps during the autopsy though made by the hands of a practised assistant. The microscope here affords valuable assistance. In the great majority of cases one has only to spread out a little of the softened tissue between a slide and a cover-glass in order to find with a quarter objective numbers of opaque mulberry-like aggregations of fatty granules, the well-known "compound granule-masses" or "corpuscles of Gluge." The exact pathological nature of these bodies is still uncertain; but there is scarcely any doubt as to their practical significance, as indicating that the part of the cord in which they are detected is in a morbid condition. Leyden, indeed, quotes statements made by different observers that they are normally present in the fœtus, and that they may also be found in persons at an advanced age, or after death from tuberculosis, pneumonia, or anæmia, when no spinal symptoms had existed during life. But at any rate one need not hesitate to regard them as a proof of disease when they are thickly scattered through some parts of a cord and absent elsewhere. The difficult question of their origin may be left to be discussed hereafter, in the section on softening of the brain. The most remarkable points about them are that they are observed under such diverse pathological conditions, and are fully developed at so early a period. Thus there were large numbers of them in the spinal cord of a patient who was under the care of Dr Frederick Taylor in Guy's Hospital in 1873, and who died within eleven days from the commencement of his symptoms, and not more than fourteen days after the occurrence of a slight injury that perhaps set up the disease. In such cases they are not generally accompanied by an obvious infiltration of leucocytes, or by the presence of any diffused granular matter, but lie embedded among nervous elements which to a superficial observer seem to be normal.

Recent investigations, however, have shown that the histological changes are really far more considerable than would at first sight appear, and it is

* Whether white softening is ever observed when death has occurred at a very early stage I am not sure. I have not found any instance of it among those cases which have proved rapidly fatal at Guy's Hospital. Although Jaccoud speaks of a *myelite suppurée* ('Les Paraplégies,' p. 545), he does not affirm the actual presence of true pus corpuscles.—C. H. F.

to be noted that granule-masses are not infrequently discovered when there is no obvious softening, the texture being, of the two, rather firmer than is natural; and, again, when there is no marked change of colour, or, at most, only a pinkish-grey tint, with some blurring of the pattern on a cut surface. Nor is even the failure to detect granule-masses a proof that morbid changes may not be recognised where the cord has been specially prepared for the purpose. In many cases after it has been soaked in a diluted solution of chromic acid for two or three weeks one can see at a glance what parts of it are diseased, since they remain colourless instead of turning green. And a microscopical examination of thin sections shows that the nerve-fibres have their axis-cylinders swollen and varicose, that the ganglion-cells are enlarged and granular, or perhaps vacuolated; and (according to Erb) that the network of the neuroglia is thickened, while its cells are increased in size and augmented in numbers, and sometimes contain more than one nucleus. Erb also says that a colloid substance is sometimes found diffused along the course of the swollen connective-tissue bundles, and Leyden that a scanty infiltration of leucocytes is now and then seen in the interstices between the nerve-fibres. Such appearances are doubtless conclusive as to the inflammatory nature of the process, and so is the presence of recently effused lymph in the tissue of the pia mater of the cord or in the subarachnoid space. This is sometimes in sufficient quantity to be plainly visible to the naked eye.

Acute myelitis is never limited to the anterior or posterior cornua of the cord, nor to any one of its columns. It is a "diffuse" or "indiscriminate process," not what the German pathologists call a "system-lesion," or, as we may say, a "columnar" disease. It may begin from the surface, in sequence to meningitis, or it may occupy the grey matter around the neural canal ("central" or "peri-ependymal" myelitis), or it may affect the entire breadth of the cord, including both cornua and columns (transverse or segmental myelitis); it may in rare cases be "disseminated;" or lastly, it may spread over large portions at once as a progressive ascending myelitis.

*Chronic interstitial myelitis.**—The disease just described does not in all cases run the course of an *acute* inflammation. Sometimes, indeed, it sets in with fever and ends fatally in a few days, but in many instances it is unattended with febrile disturbances, and goes on for many months before it terminates, either in the death of the patient or in his more or less complete recovery. What justifies the name of acute softening or acute myelitis is the fact that its onset is more or less sudden and its development rapid, so that the paralysis is complete within a week or two.

In marked contrast with the most protracted cases of the disease just described is one which always begins insidiously and gradually, of which the duration is never less than two or three years, and which, instead of leading to softening of the cord, rather renders it firmer and harder than before. The naked-eye appearances in this form of myelitis are variable. Sometimes it is altogether impossible to distinguish those parts of the cord that are diseased from those that are healthy; in such instances no morbid change was recognised until the accurate microscopical investigations of the last few years revealed its presence. In other cases the substance of the cord is obviously tougher than natural. Ollivier long ago aptly compared it to boiled white of egg; the knife meets with resistance in cutting through it,

* *Synonyms.*—Sclerosis of the cord. Grey induration.

and the exposed surface is smooth and even. On close scrutiny it often looks gelatinous, and has a greyish or greyish-yellow tint, instead of the milk-white colour of a healthy cord. It is rather shrunken than increased in size. When held up to the light the diseased parts are translucent. They are untouched by osmic acid, and when stained with carmine they take the colour much better than the unaffected white columns.

With the aid of the microscope the neuroglia is found to be thickened and to have a fibrillated texture, or even, in extreme cases, to be converted into a dense mass of connective tissue with delicate parallel, wavy fibres. Its cells and nuclei are increased in numbers, and are far more conspicuous than in the healthy spinal cord. Cells possessing a large number of radiating processes (Deiters' cells) are often seen; it is said that similar cells may be discovered in the normal neuroglia, but they are at any rate much more obvious in cases of chronic myelitis. The nerve-fibres are generally atrophied; they have lost their medullary sheaths, and their axis-cylinders are described as having a hard, glistening look. The ganglion-cells are shrivelled and granular, or may be converted into homogeneous, bright-looking, angular bodies without processes, and having apparently no nuclei, so that they can hardly be identified. Corpora amylacea are generally abundant, and at the same time granule-masses are present, often in large numbers, but sometimes very few. The smaller blood-vessels are thickened.

This morbid process is now generally known as "sclerosis." It is not, however, peculiar to cases of diffused or segmental chronic myelitis attended with paraplegia, but lies at the foundation of several other affections of the spinal cord, which will be described separately, because their limitation to special parts of its substance gives them an independent place in nosology. In the cases now under consideration the lesion so far extends over the segmental area of the cord that it interferes with or altogether prevents the transmission of motor impulses from the brain to the parts below. Its longitudinal extent varies greatly. Sometimes it is confined to a single spot, and it is often spoken of as "chronic transverse or segmental myelitis;" sometimes it advances slowly along the entire length of the cord (generally from below upwards) until it reaches the bulb. These are the cases known as "creeping palsy."

Ætiology.—According to Erb, inflammation of the cord is more frequent between the ages of ten and thirty years than in older persons. But twenty-five consecutive cases of fatal primary diffused myelitis at Guy's Hospital were pretty uniformly distributed over the several decennial periods from ten to fifty, and three of them occurred in patients between fifty and sixty years old. It is certainly a rare disease in children and in old people—as would be supposed from the nature of its antecedents. Most cases occurred in men, the proportion being 19 to 6. This, probably, depends on the fact that men are much more exposed than women to its various exciting causes. For, although myelitis is certainly not always due to any one morbid influence, its exciting cause can often be traced.

Sometimes it is the result of *exposure to cold*, particularly to wet. Several instances of this have been published,* and our records at Guy's contain others scarcely less striking. Thus, in 1876, a Custom-house officer was admitted

* See, for example, the first three of Dr Bristowe's cases ('Brit. Med. Journ.,' 1888, ii, p. 1369).

into the hospital with nearly complete paraplegia, who had been well until eight days previously, when he was obliged to remain for twenty-four hours in a barge, where everything was soaking wet. On the very next day he was attacked with pains in the joints, which he believed to be rheumatic; his urine began to run away from him; and two days later his feet and hands and back already felt numb. Another patient, who was brought in on January 29th, 1875, had on the 18th of that month got wet and caught cold; three days afterwards he passed his water into his bed without knowing it, and his legs became numb and powerless. Cases of acute myelitis have followed sleeping on the damp ground or in snow and prolonged immersion in water, as when a person narrowly escapes drowning. Ditchers and other men who work up to their knees in water, and women who have tramped through rain till their skirts are soaked through, seem particularly liable to this disease.

Great *bodily fatigue* also seems often to play an important part in the ætiology of the disease. When it occurs in soldiers on active service, as is said to be frequently the case, it may either be due to exhaustion of the spinal cord from forced marches, or to exposure to cold and wet, or to both causes combined. A case in point has been recorded by Sir William Gull ('Guy's Hosp. Rep.,' 1856, Case 10). A young man, after walking twenty-eight miles to seek for work, passed the night of July 8th, 1855, in a brick-field. On the 15th he walked thirty-two miles; the day was wet, and he allowed his clothes to dry upon him. Next day he felt as well as usual, but in the afternoon, while he was sauntering in a garden, his legs suddenly gave way under him, and he fell down. He was admitted, six days later, completely paraplegic. He was healthy and florid-looking; but it should be stated that he had, about a fortnight previously, been unable to pass his water for a period of twelve hours. He died in less than a month.

A great muscular effort, such as often causes a pain in the back, is now and then followed, after an interval of a day or two, by paraplegia. An instance of this has already been cited (p. 438) in the case of a dock labourer. Another example of it occurred in Guy's Hospital in 1863: a railway porter, aged thirty-two, was pushing a carriage with his back, when he suddenly gave a jump to escape falling into a pit, and so ricked his spine; for a moment he felt powerless, but was able to resume his work, and worked as usual on the next day; on the day after, however, he was walking in the street, when he suddenly became paralysed and fell down. Both these cases ended fatally in about six weeks; at the autopsy no injury to the bones or the ligaments could be discovered; but in the dock labourer there was softening of the cord in the dorsal region, and the affected part had a greenish colour, from the presence of extravasated blood. The microscopical examination revealed no further proof of inflammation; but if modern methods of investigation could have been used, we might have been more successful.

Again, it occasionally happens that paraplegia develops itself as a sequel or complication of *a specific fever*. Virchow has recorded ('Ges. Abhandl.,' p. 683) an instance in which chronic myelo-meningitis came on a few months after recovery from enteric fever. Westphal examined the bodies of two patients, who became paraplegic during the eruptive stage of smallpox, and in both cases he found disseminated myelitis.

Either *pregnancy* or the puerperal state, too, may be attended with paralysis of the lower limbs. A woman is at the present time (Dec., 1889)

in Mary Ward who is slowly recovering from complete paraplegia, perhaps due to myelitis, which followed severe puerperal convulsions with albuminuria. In one remarkable case of acute myelitis, which ended very quickly in death, Baumgarten found the characteristic bacilli of anthrax in the blood as well as in the spinal cord ('Arch. f. Heilk.,' 1876).

Erb, with many others, believes *syphilis* to be an undoubted and frequent cause of myelitis, and states that the affection may run either a very rapid or a chronic course. That acute paraplegia often follows syphilis there is no doubt; the only question is whether it is due to myelitis (*v. infra*, p. 459).

Lastly, there is reason to believe that *sexual excesses* play a considerable part in the ætiology of diffused myelitis, although it is very difficult to say exactly how large. Men who have been indulging their passions too freely, especially if they are weakly or very young, often experience pains in the back and limbs, which seem to be due to exhaustion of the lower spinal centres, and it is possible that these symptoms may pass into those of actual myelitis.*

Clinical history.—The symptoms of *primary, acute, diffused* myelitis, are first those of paraplegia as above described, including retention of urine and other pelvic symptoms.

Beside, however, causing akinesia, impairment of sensation, dyssesthesiæ, disorder of the reflex functions of the cord, and the like, myelitis is often attended with another set of symptoms, namely, *painful sensations* referred to various parts of the body. In some instances the seat of pain is in the back; it there varies greatly in intensity; it may either be confined to one or two spinous processes, or diffused along the whole length of the cord; there may be extreme tenderness on pressure, or this may be altogether absent. Occasionally spinal pain may be the earliest symptom of the disease, but in the author's experience this is rare. In other instances the pain is referred to the front of the chest, or to the epigastrium, or to one or more of the limbs. One patient, a girl of nineteen, was attending as an out-patient for pain in the chest, when she one day fell down in the waiting-room, struck with paraplegia. Another, a man aged forty-nine, had complained of a fixed pain in the left hip for eight weeks before any definite sign of spinal mischief showed itself. A third, a man aged fifty-one, suffered at first from severe burning pains in the soles of the feet, which continued night and day for a considerable time. These cases all terminated fatally, and in each of them the bones and ligaments and meninges were found to be healthy, and the disease to be limited to the substance of the cord itself.

Sometimes, when pain is referred to the fore part of the body, it is accompanied by a sense of constriction, as if a cord were tightly bound round the waist, or as if the chest were fixed in a vice. We shall hereafter see that this symptom, to which German writers give the special name of *Gürtelgefühl* (girdle-feel), is particularly marked in that other form of paraplegia due to compression of the cord by disease of the surrounding structures. But undoubtedly it occurs now and then in cases of primary myelitis.

* Whether coitus in the erect posture is especially injurious I do not know, nor whether onanism is so, except in so far as it is apt to be repeated frequently, without instinctive desire, and at an early period of life. On these points there is no evidence, nor can one desire to collect it, since, whatever the physical injury of such practices, it is far outweighed by their moral evils.—C. H. F.

The majority of cases of myelitis are altogether unattended with either pain or girdle-feeling.

The *course* of myelitis differs widely, not only according to the nature and seat of the morbid change in the cord, but also in individual cases which appear to resemble one another closely. Erb speaks of the disease as sometimes setting in with malaise and fever, and even with rigors. A case in point occurred at Guy's Hospital in 1872. A man aged fifty-one, who was much exposed to weather, one day began to shiver, and was attacked with severe pains running down the back of the thighs and calves, and the insides of the arms. He remained in bed for four days, after which the pains left him, and he went to work again. Next day he lost all power in his limbs, and he died of dyspnœa about eight days afterwards. Paralysis often shows itself suddenly in that form of myelitis which leads to "softening" of the cord. Indeed, as Erb remarks, the rapid development of this symptom is almost the only reason for calling cases of this kind "acute," since they are often unattended with febrile symptoms, and their duration may be prolonged over a period of many months. In most cases of acute myelitis, however, death takes place in a few days or two or three weeks. It is comparatively rare for the disease to be prolonged in a chronic form, and then also it is almost always fatal.

Prognosis.—Until within the last few years there were no grounds upon which writers could speak with confidence of the possibility of complete recovery from myelitis. It was well known that many patients suffering from paraplegia got perfectly well, but whether inflammation of the cord had existed was uncertain.*

An observation made by Michaud, on a woman who died from caries of the hip and vertebræ, shows that, in spite of the occurrence of well-marked myelitis, recovery from paraplegia due to external compression may take place, though the affected part of the cord retains signs of a morbid change. This case may perhaps be taken as proving the possibility of complete subsidence, with return of normal function, of those local and slight forms of myelitis which we may suppose to be present in partial and transitory forms of spinal paralysis. This conclusion is further supported by the fact that in such cases recovery is often incomplete; since it is more reasonable to suppose that an organic affection of the cord may subside than that a merely functional disorder should be permanent.

The prognosis is generally unfavourable when there is complete paraplegia with pelvic symptoms; but even to this rule there are some remarkable exceptions. Two have been recorded by Wilks in his 'Lectures on Diseases of the Nervous System.' One is the case of a gouty man, aged fifty-two, who had been losing power over his lower limbs and his bladder for a fortnight, so that on admission into Guy's Hospital he could not move his legs, and had partial loss of feeling up to the umbilicus. Reflex movements persisted. The urine, which was ammoniacal, had to be drawn off twice daily. Afterwards he had a feeling of tightness round the lower part of the chest and the abdomen, and he experienced numbness

* Eichhorst and Naunyn found in experiments upon young dogs, that after they had cut through the spinal cord in the lower dorsal region the lesion was slowly and partially repaired; a few nerve-fibres with double contour were developed in the new material which filled up the gap, and motor power and sensation were to some extent regained. These results, however, have not been confirmed by the more recent investigations of Goltz and Freusberg, and it is certain that in man the cord is far from possessing such powers of restoration.

of five months she was discharged perfectly well. Dr Wilks,
rejects hypotheses of reflex paraplegia and of anæmia or
the cord, confessed that he does not know what was the
disease in these two cases.

The following case of apparently acute anterior myelitis
recovery.

The writer saw in January, 1888, with Dr Cock, of Peckham
years old who a week before had been unable to pass his water
off, and there has been more or less incontinence since. Three or
his legs began to feel weak. When seen he was almost compl
below the waist, with sensation unimpaired, the knee-jerk ab
plantar and cremasteric reflex almost absent. He had scarcel
expel either urine or fæces. There were no convulsions, and
nor pain of any kind. Sensation was apparently normal, so
ficult to fix the upper limit of paralysis. The next day pri
and bullæ appeared on the paralysed legs. The tempera
normal or subnormal. There was no tenderness along the
pressure or to contact with a warm sponge. The paralysed
to faradism as well as to interrupted galvanism. In a week
of the attack there was some return of power in the leg
symptoms gradually disappeared, and he at last recovered
about two months' illness.

Diagnosis.—The decision that myelitis is the cause of part
paraplegia is generally effected by a process of exclusion.

For practical purposes we must first exclude mere shamm
paraplegia—hysterical, alcoholic—and paraplegia due to
peripheral neuritis. The presence of "pelvic symptoms"
generally suffice for this. Next we must exclude "extrinsic
compression of the cord, and chronic and spastic cases of slo

Lastly, we have to decide which intrinsic disease of th

likely to be the cause of the paralysis. Myelitis is at once the most frequent of these affections, and by far the most varied in its symptoms and course.

The occurrence of paraplegia in a person known to be suffering from phthisis or any other tuberculous disease would lead one to suspect *caries of the vertebræ* producing compression of the cord without deformity. It is impossible to distinguish the paralysis caused by a *tumour* within the cord from more common cases due to circumscribed transverse myelitis; but the latter is the more likely. Severe and long-continued pain would probably lead one to suppose that the lesion was in the *bones* or in the *membranes;* but, as we have seen, acute myelitis sometimes causes pain. In two of the cases of paraplegia on which this chapter is founded *hæmorrhage* was, in fact, correctly diagnosed; but, taking into consideration its extreme rarity, perhaps both of them were as likely to have proved myelitis, for suddenness of onset is not of itself a sufficient ground for attributing paraplegia to effusion of blood. As regards *syphilis*, its recognition as the cause of paraplegia must be based upon the clinical history and upon the presence of other syphilitic lesions rather than upon any peculiarities in the spinal symptoms themselves; and no doubt, as with other remote effects of the venereal poison, there are many instances of syphilitic paraplegia in which the most careful scrutiny would fail to elicit proof of their real nature.

There is one positive indication of myelitis that must always be carefully sought, namely, gradual creeping up of the paralysis and anæsthesia from the thighs to the groins, and from thence to the abdomen; it warrants a confident diagnosis of diffuse ascending myelitis. Its early stage is probably indistinguishable from Landry's paralysis (*infra*, p. 456); but after a time the integrity of the recto-vesical functions, and the other negative characters would differentiate the latter.

The diagnosis between myelitis and other varieties of paraplegia, particularly hysterical, alcoholic, and other *functional* cases, on the one hand, and those which depend on *external compression* on the other, will be further referred to under their several heads.

Treatment.—The question remains, whether we can by medical treatment influence the course of myelitis so as to increase the proportion of cases in which recovery occurs; and here we have little positive knowledge to guide us. Of late years it has not been the practice in England to adopt active measures for the acute form of myelitis. The modern German plan seems to be to use leeches or cupping-glasses freely, to apply bags of ice along the spine, to rub in blue ointment or to give calomel internally—in fact, to carry out the "antiphlogistic" treatment very much as English physicians used to employ it thirty years ago. In proof of the value of *ice-bags* a case recorded by Dr Tibbits, of Clifton ('Med. Times and Gaz.,' 1871), is quoted: that of a man suffering from myelitis, which was rapidly spreading upwards, which had already produced paralysis of the arms, and which was attended with a temperature of 103·6°, while the pulse was 132, and the breathing 40 in a minute. Soon after trial was first made of the cold applications he became easier; the temperature fell to 99·2°, the pulse to 100, and the respirations to 24. In the course of the next ten days he completely regained the use of his arms, but no recovery of power took place in the parts which were first paralysed, and he died six weeks later of exhaustion from bedsores. Possibly the issue of the case might have been more favourable if the ice-bags had been employed earlier; paralytic symptoms had been coming on for twelve days, and there had been

complete paraplegia for eight days. Erb recommends blisteri
and even the actual cautery, in spite of the risk of setting
which he fully recognises.

It is of great importance for the patient from the first to be
a water-bed. He should not be allowed to lie constantly on
should be shifted from time to time. It is sometimes danger
him to sit up. Some years ago a man, who had recently be
into hospital with symptoms of acute myelitis limited to the
the cord, was taken out to have his bed made. When put bac
much exhausted, and soon afterwards he died.

In some of the less complete and acute forms of mye
evidence of the value of *ergot* administered internally; Hamm
case which he considered to be one of "congestion of the
which it seemed clearly to be of great service. The patient
affected with partial paraplegia, and afterwards with paralysis o
from exposure to cold and damp. He was unable to walk u
crutches and had a man on each side holding his shoulder. H
constant dull aching pain in the loins, and occasional starting
while in bed. Under treatment by the extract of ergot (
recovered in a month. He had a relapse a few weeks later, b
in ten days under the same treatment.

The tincture of *belladonna* in fifteen minim doses is said to be useful in similar cases, especially when there is severe pain in the back.

When there is evidence of syphilis, there is little doubt that active mercurial treatment of myelitis by inunction or otherwise is of value; and in more chronic cases of paraplegia following syphilis the Liquor Hydrargyri Perchloridi is sometimes of service.

Many writers recommend full doses of iodide of potassium, not only when there is probability of syphilis, but in other forms of myelitis.

Galvanism should not be employed early in cases of myelitis, but it is probably useful and certainly harmless after the paraplegia has lasted for several weeks and acute symptoms have subsided. The electrodes should be large sponges placed at a considerable distance apart, one upon the neck, the other over the lumbar vertebræ; they may in turn be moved gently up and down, and the direction of the current may be from time to time reversed. When there is reason to believe that the disease is limited to a segment of the cord, one pole may be placed on the affected spot, the other over the front of the chest or of the abdomen. Faradisation of the paralysed muscles may be useful if they are flabby or wasted.

Strychnia is of doubtful value in the later stages of myelitis, and is certainly harmful before.

On the Continent certain spas have great reputations for the treatment of the more chronic forms of paraplegia, with what amount of justice it is hard to say. Erb says that hot baths are apt to be injurious, except at very advanced periods of such cases. Among the places most frequently visited by patients suffering from paralysis are Schlangenbad, Ragatz, Pfeffers, Gastein, Wiesbaden, Teplitz. It is said that in proportion as the elevation above the sea is greater, baths can be borne at higher temperatures without ill effects.

There are two anatomical conditions which, like myelitis, may produce paraplegia of intrinsic origin. Both are rare; and difficult or impossible of recognition during life. They naturally follow the above account of myelitis, which they resemble clinically.

Hæmorrhage into the cord. "*Hæmatomyelia.*"—As a primary cause of paraplegia this is so rare, that Hayem* endeavoured to show that in all the supposed cases which have been recorded since those of Ollivier and Cruveilhier, there was antecedent softening, the result of myelitis. This view would dissociate it altogether from the common cerebral hæmorrhage of old people; but there certainly seem to be some instances in which extravasations of blood into the spinal cord and those into the brain are strictly comparable. A case in point is one of Jaccoud's—that of a woman, aged sixty-two, who was brought into the hospital with complete paraplegia, which had suddenly appeared four days before. The diagnosis was given that there was hæmorrhage into the lumbar enlargement of the cord. Six days afterwards she was found dead in her bed. The autopsy showed that the grey matter of the cord, up to the highest roots of the lumbar plexus, was occupied by a clot which was beginning to undergo disintegration. The cause of death was an immense effusion of

* His monograph, 'Des hémorrhagies intrarachidiennes,' 1872, contains a collection of thirty-two cases with copious references. Goltdammer finds about thirty cases recorded of non-traumatic hæmatomyelia, most of them hæmorrhagic myelitis ('Virchow's Archiv,' lxvi).

blood into the left lateral ventricle, the crus cerebri, the bulb. Erb says that the part of the cord into which hæmo apt to occur is the central grey substance. Sometimes the b throughout its whole length; in other cases it destroys the of the cord at a certain level.

This affection is believed to be less rare in men than in wom the ages of fifteen and thirty-five than at a later period of li instance is recorded by Goltdammer ('Virchow's Archiv,' between fifteen and sixteen years of age. She was one d sitting quietly on a chair, when she suddenly experienced a pain in the back between the shoulder-blades, which compel out. The pain quickly passed into the right arm, and the arm and the lower part of the chest: at the pit of the stom round the body like a girdle. She fell from her seat, and that she could not move her right leg; half an hour later was paralysed; within two hours she was taken into the ho found to be perfectly paraplegic, with anæsthesia up to the n of power over the bladder. Reflex movements could be lower limbs. The case was diagnosed as one of hæmorrhag below the cervical enlargement. She lived almost exactly a autopsy there was found a firm cicatricial mass in the grey stance of the upper part of the dorsal region of the cord elements were completely destroyed; hæmatoidin crystals an ment were present in large quantity, giving a reddish-brown

A few years ago a healthy labourer was admitted into under the writer's care, who after a sudden and severe eff give way under him, and became completely paraplegic with two. There was no pain, no sign of local injury, and steadily recovered. The suddenness of the attack, the com and the complete recovery seemed to point to hæmorrhage in meninges.

Hæmorrhage into the cord, though often fatal, may repaired by absorption of the clot. A remarkable case in which, after severe symptoms terminated favourably, is rec (vol. ii, p. 154). It is doubtful whether any special treatme

Tumour within the cord.—For practical purposes one may this head syphilitic gumma and also tubercle of the cord, j class them with tumours of the brain. Still, the group is a

A *gumma* very rarely begins in the cord itself; it is far (or rather, less rare) in the meninges.

Tubercle in the cord forms a rounded or elongated mass, reaches any considerable size. Two cases were observed in in the year 1870; in one the tubercle was no larger than a p it was compared to a small cherry.* The main substance of a is firm and caseous; its centre may be softened into a crea periphery is sometimes grey, showing a well-marked lymphoi is surrounded by a soft, vascular, pinkish zone, so that it rea

* It is worthy of note that in one of them no sign of the lesion surface of the pia mater. I made a series of sections at the usual di another, and missed it altogether; it was afterwards found by Dr Regin cutting across the cord in fresh places.—C. H. F.

its bed when it has been cut across.* In two cases at Guy's Hospital there was extensive pulmonary phthisis; in a third the peritoneum was tuberculous, and the mesenteric glands were caseous.

If not tubercle, a growth in the cord is probably a *glioma;* for an intrachordal sarcoma is almost unknown; one that was found in the body of a woman, aged twenty-six, at Guy's Hospital in 1860, was an oval soft mass made up of spindle-cell tissue. Such tumours are somewhat apt to undergo mucous softening (myxoglioma). This may probably be the origin of some instances of the remarkable cysts which are occasionally discovered as an elongated cavity in the centre of the cord. It looks like a dilated central canal (*hydromyelus*), but is really not so, as is proved by the fact that in transverse sections the remains of the canal can still be seen in front of it. This condition is described under the name of *Syringomyelus.* Dr Frederick Taylor showed a beautiful specimen in which no clear indications of the presence of a new growth could be made out ('Path. Trans.,' 1878 and 1884). Probably when not a new growth, it is a congenital malformation.

The symptoms produced by tumours of the cord vary widely in different cases. As a rule, paraplegia is present and differs in no respect from that dependent on any other cause. But sometimes the paralysis is of a more limited kind. In a case under the writer's care in Stephen Ward (Nov. 1878) the tumour (a glioma) occupied the cervical region of the cord and caused acute hæmorrhagic myelitis around it. The symptoms were paraplegia and cystitis with paresis of the right arm, and the temperature rose to 108·5° F. shortly before death. Theodor Simon has recorded several remarkable cases in which there would appear to have been a complete absence of all symptoms ('Arch. f. Psych.,' 1874).

Tumours of the meninges producing paraplegia by compression of the cord are not so rare as growths in the cord itself (v. p. 485, *infra*).

There are certain groups of paraplegic cases which are at present without any known morbid anatomy; some are toxic, others functional, but since all of them are believed to have their cause and seat in the cord, their description naturally follows that of intrinsic paraplegia.

Anæmia of the spinal cord.—Unless the modern interpretation of a very old observation is incorrect, one of the possible causes of paraplegia is an arrest of the arterial blood supply to the lower part of the cord. Nicolas Steno in 1667, and Haller afterwards, stated, that after tying the abdominal aorta in animals, the lower limbs became powerless, and remained so until the ligature was removed. This experiment was long afterwards again repeated by Sir Astley Cooper and by others; but until 1869 the explanation universally accepted was that the muscles were paralysed because they and the peripheral nerves were deprived of blood. Schiffer, however, has recently shown that if this were the case an interval would elapse, instead of the effects being observed a few seconds after the operation. Whether a similar form of paralysis is ever seen in man as the result of disease appears to be somewhat doubtful. The most frequent cause of

* Leyden says that tubercles more often occur in the upper than in the lower part of the cord. But of three cases of which I have notes there are two in which the lumbar region was the seat of the disease, while in the third it was in the lower dorsal region. Two of the patients were women, aged twenty-eight and fifty-eight; one was a man, aged thirty-six. Dr Frederick Taylor has told me of a case that he saw in a child.—C. H. F.

obstruction of the abdominal aorta is embolism; but in th
might be expected, the clot becomes impacted close to the bi
vessel—too low to interfere with the circulation in the lumb
of the cord.

In the 'Guy's Hospital Reports' for 1857, Sir William
clinical history of a patient whose aorta was from some
obstructed, and who was attacked with paraplegia, which
peripheral, rather than spinal. The man was a shipwrigh

that there was no pulsation in the abdominal aorta, nor in
the lower limbs. The right superior epigastric artery was alr
enlarged, and could be seen pulsating. In the course of the
years he regained power to walk tolerably well, but at the en
his gait was still languid, and from time to time he had sli
weakness and numbness in the legs. His feet also were c
Using the legs brought on increased weakness and numbness.

An intermittent form of paraplegia has been noticed in hor
of obstruction of the aorta; a loss of power in one or both
limbs coming on when they are driven, and subsiding wh
still. Charcot is said to have observed a similar condition in a
right common iliac artery was obstructed. When this man
he was obliged to stop every fifteen or twenty minutes, c
paralysis of the corresponding limb; after a few minutes' rest
passed off and he was able to go on again.

Leyden found capillary embolisms in the cord in ulcerative
but no impairment of its functions had been traced to th
quotes a single case from Weiss in which a lad suffering
tive endocarditis was attackedby myelitis which was prob
embolism.

There is some evidence that a defective supply of blood
cord may lead to the occurrence of paraplegia in persons who
severely from hæmorrhage, or who are highly anæmic. Amo
of this kind quoted by Leyden there is one of a woman, aged
who had lost blood profusely after a confinement; she was exce
but she was resuming her domestic duties when, at the en
month, she suddenly became unable to stand. Another case,

* Leyden has suggested in reference to this case that a sudden obstructi
minal aorta could scarcely have occurred without more serious symptoms d
selves, and that a collateral enlargement of the epigastric artery would h
seen at so early a period afterwards. It must be admitted that the case r
"coarctation of the aortic arch" in many respects; among others, in the p
tolic murmur at the lower angle of the left scapula. On the other hand, th
tomoses over the back and the abdomen underwent gradual enlargement whi
observation. And even if the obstruction had existed long before the para
appeared, it still may have caused them; for a supply of blood adequate
requirements of the lower limbs (or, on the other view, of the spinal cord)
insufficient for some specially prolonged effort, or when the man was exhaust

Dr Moutard Martin, occurred in a man as the result of severe hæmorrhage in the course of dysentery. Others were in persons who had suffered from menorrhagia, but it must have been difficult, if not impossible, to exclude hysteria, which, as we shall presently see, may itself cause paraplegia. The same source of fallacy exists in reference to those cases which are recorded as examples of paraplegia due to chlorosis in women. Paraplegia has not hitherto been observed in the intense and fatal form of idiopathic anæmia to which men are liable as well as women.

But, after all, the mere fact that persons who have lost blood are now and then attacked with this form of paralysis is far from showing that anæmia of the spinal cord is capable of directly producing the effect in question. For the proof to be complete there must be no interval of time during which impairment of the nutrition of the cord could have occurred as an intermediate link in the chain of events. In any future case it would be important to note whether the patient, after the hæmorrhage, took violent exercise or worked hard in any way, using his legs more than his arms, so as to cause the lower spinal centres to make special claims upon the nutrient powers of the blood. We might thus be able to see why the lower limbs should alone be paralysed, and not all parts of the body alike.

Some years ago Brown-Séquard professed to be able to distinguish paraplegia due to anæmia from that due to hyperæmia by the simple test that, whereas the former was benefited by keeping the patient recumbent on the back, the latter underwent aggravation when this posture was adopted, but was lessened if he lay on the abdomen, or stood upright, or walked. This method of diagnosis has been endorsed by Dr Hammond, of New York, who mentions a case which he considered to be one of congestion, and in which "all the symptoms were worse in the morning;" but the value of his opinion is diminished by the readiness with which he adopts this kind of hypothetical pathology, and assumes the existence of two distinct forms of spinal anæmia—the one limited to the antero-lateral, the other to the posterior columns. The last affection is one with which we are all well acquainted under the name of "spinal irritation" (or rachialgia); and we have a striking proof that such speculations are baseless in the fact that Stilling and Ollivier both referred this disease to the very opposite condition —congestion of the cord—for reasons which are neither better nor worse than those of Dr Hammond.

Divers' palsy—caisson palsy.—It has repeatedly been observed that men who work at considerable depths under water, as in searching wrecks and sinking the caissons for bridges, are liable to lose the power of their legs after coming to the surface. The paraplegia seems to be chiefly or entirely motor, and usually passes off without leaving traces behind. It has been plausibly attributed to the increased pressure on the surface gradually driving the blood from the surface into the great vertebral plexus of veins, and upon the more rapid return to the surface producing a sudden reflux towards the skin, and temporary anæmia of the cord.

Hyperæmia of the cord.—All pathologists are agreed that distension of the blood-vessels within the spinal canal, if found in the dead body, affords no proof that they were over-full during life; it may be due either to the mode of death, or to gravitation afterwards.

There are sometimes good reasons for believing in the occurrence of morbid processes, in spite of the fact that they cannot be recognised by the

anatomist. But there are no such reasons for recognising h congestion of the cord as a permanent morbid condition. I days of pathology, writers assigned all diseases their anatomi an ascending order of severity. They found that almost eve liable to certain chronic changes which could be regarded as i and any cases which seemed to stand lower in the scale were hyperæmia or to anæmia, according as the one condition seemed the more easily to be brought into harmony with symptoms.

Even now a similar method prevails. In 1866 Dr Radcliffe System,' ii, p. 619) had under his care a woman who had paralysed in all her limbs the morning after having had her m checked by an alarm of fire. Among the other symptoms we the fingers and toes, some degree of general hyperæsthesia burning aching in the limbs and along the spine, without speci on pressure over the vertebræ, but with increased sensitive sponge. The bladder and rectum performed their functio There was no over-excitability of the reflex centres in the low cord. Within two or three weeks she began to improve, and five months she left the hospital convalescent. Considering stances under which her attack commenced, we can see that t of spinal congestion is not unreasonable, although other inter possible.

It is easy enough to pick out cases of paraplegia present symptoms as those of Dr Radcliffe's patient, and to label them but no ground appears for giving to these cases the title of spin rather than to others in which the paraplegia is incomplete a in recovery. Dr Radcliffe laid stress upon the sudden comm characteristic; while Erb affirms that a *slow* development of t distinguishes hyperæmia of the spinal cord. He also mentions, most important signs of this affection, its fluctuating and chang but in some cases of myelitis inexplicable variations in the de paralysis and anæsthesia occur from day to day.

Concussion of the cord.—In ordinary cases of fracture and the spine, such as come under the care of the surgeon, the pa is commonly present from the first, is attributed either to cr cord by a displaced vertebra or to effusion of blood.

A case recorded by Gull shows how a comparatively slight ac attended by fatal consequences in this way. A man was carryi back down some cellar stairs when his foot slipped, so that he fell of coals upon him. He died in thirty-four hours. Two of the cer were found torn asunder, but this was not the cause of the pa which he had suffered immediately after his fall, for there was no of the bones nor any injury to the posterior ligament of the spin There were, however, several spots of ecchymosis in the posteri of the cord, as well as in the posterior white columns and the of the left lateral column. It is perhaps worthy of notice th lesions did not actually explain the paraplegia, for there is no motor tracts on both sides were injured. This, however, illus the view which should be taken of capillary ecchymoses o centres, whether cerebral or spinal. It is not that they thems

paralytic or any other symptoms, but that their presence, showing that the violence was sufficient to tear asunder vessels, shows also that it must have been enough to lacerate the nervous elements themselves, which are more delicate.

These considerations tend to explain the fact that spinal injuries are sometimes followed by paraplegia, and may even terminate fatally without any morbid change whatever being discoverable even with the microscope. Leyden says that he met with an instance of this kind in which death occurred within five days, and in which he failed to detect any lesion, even after having hardened the tissues with chromic acid. Such cases are commonly described as cases of *spinal concussion*, and it is probable that they depend upon a molecular change in the nerve-fibres and cells of the cord due to the jarring force of the injury. The occurrence of this change would of course be prevented if the vibrations should in any way be hindered from reaching the nerve-centres. Mr Erichsen, for instance, says that after a railway accident those persons who are sitting with their faces to the engine are less likely to suffer from spinal injuries because they would be thrown forwards and could break their fall with their arms and hands, whereas those who sat the other way would be driven against the back of the carriage when its motion was suddenly arrested so that there would be scarcely anything to prevent the spinal cord from being violently shaken.

The cases of which one can most confidently speak as being examples of concussion of the cord are those in which a blow or a fall is instantly followed by paralysis, and in which recovery takes place so rapidly that the alternative diagnosis—hæmorrhage—can be satisfactorily rejected. Such an instance perhaps is one related by Erb. A man, aged fifty-five, fell twenty feet from a tree upon his heels and ischia. He was not unconscious, but was at once unable to walk, and had to be carried home. He experienced severe pains in the sacrum and in the lower limbs, but these passed off after a time. There was no loss of sensation, but the legs were said to be entirely motionless for a week. When he came under medical observation at the end of four weeks he could only make a few steps at a time, and slowly and with hesitation. Reflex movements could be produced as usual. The excitability of the nerves and muscles by electricity was much diminished. Galvanic treatment, applied both to the spine and to the legs, was attended with great success. He was soon able to walk well, and in three weeks he was discharged cured.

But in most cases in which railway accidents are followed by paralysis this does not manifest itself until some time has elapsed. The interval is often of several days' duration, and Mr Erichsen says that it may even last two or three months. During this time the patient is not, indeed, well; he is suffering from other effects of the injury, but he frequently has no idea that his spine has been hurt.

It is difficult to see how the diagnosis of "concussion" is to be established as against that of myelitis, when the symptoms are thus remote. However slight they may be, one may surely conceive them to be caused by an inflammation of the cord limited to a sufficiently small area of its substance. And the fact that they generally subside after a time affords no argument to the contrary, now that we know that myelitis is a disease from which recovery is possible.

SCENDING PARALYSIS.*—Diffuse myelitis so
ds along the cord, and destroys life in a few
re not very infrequent, the name of acute asc

* *Synonym.*—Landry's paralysis. Poliomyelitis anterior acutissima wa
on a wrong diagnosis of its nature, both clinical and pathological.

Kussmaul's two cases of "Fatal Paraplegia without assignable cause"
were published in the same year as Landry's paper. The account of Lan
in the text is founded on the statements by Erb, Eichhorst, Ross, and
Remak's article "Spinallähmung" (p. 651) in Eulenburg's 'Real-Encyclopä

Neither Dr Fagge nor the present writer ever saw a case, and one or tw
Dr Ross appear to be all that have occurred in England during thirty years.

course contain at each level fibres belonging to all parts of the body below. It is doubtful whether these cases can fairly be brought within the narrow definition of Landry's paralysis recognised by systematic authors; they only resemble the typical cases in there being no recognisable lesion, and in the sensibility of the paralysed parts remaining perfect.

The most remarkable and characteristic features of the disease are these two. The affected limbs lie flaccid and free from spasm. At first reflex movements can be excited; after a few days both superficial and "deep reflexes" are lost; but the electrical contractility of the muscles persists to the last, nor do they waste. The functions of the bladder and rectum are unimpaired; there may for a time be retention of urine, but this quickly passes off, so that a catheter has seldom to be used. The patient may complain of slight feelings of numbness, or of formication, but the paralysed parts are still sensitive to touch and to painful impressions. No pains are experienced in the affected limbs, nor is there any tenderness of the spinal column. The patient may be so completely free from discomfort, and from all the ordinary signs of serious illness, that it may be difficult for those about him to realise the gravity of his state. In one of Landry's original cases, M. Gubler thought for a day or two that the paralysis was feigned, nor was there any apprehension of danger when the patient was within eight hours of death.

Pathology.—Morbid anatomy has hitherto thrown no light whatever upon the nature of this disease. Westphal ('Arch. f. Psych.,' 1876) examined the spinal cord by the most approved methods in three typical cases, and with absolute negative results. The same result followed autopsies by Vulpian and Hayem.

Before, however, accepting any but an organic change as the origin of the symptoms, it would be necessary to examine the whole of the motor tract, including the anterior roots of the nerves.*

Westphal supposes that the affection of Landry may be due to the operation of some hitherto unrecognised poison; others suggest the presence of a microbe; and Erb thinks that its nature is the same as that of tetanus—an analogy which explains very little.

There is no febrile reaction, but Westphal observed the spleen to be enlarged, and this has been regarded as evidence of the malady belonging to the group of "blood diseases."†

Prognosis.—The mean duration of fatal acute ascending paralysis is said to be from eight to twelve days. It has been known to destroy life in two or three days, but sometimes it runs on for as many weeks, and may end in the patient's recovery. Landry spoke of eight out of his total of ten collected cases (only four of which he had seen himself) as having terminated favourably; but his paper contains no details to justify the diagnosis. Erb says that the disease may stop at any period of its course, even when respiration and deglutition are affected.

Ætiology.—With regard to its causes, nothing is known. It appears to occur mostly in young adults, and more frequently in men than in women,

* Since the above was written, Nauwerck and Barth have published, in the fifth vol. of Ziegler's 'Pathologische Beiträge,' a case of Landry's acute ascending paralysis, in which they found after death the cord normal, but neuritis of many of the nerve-roots and extensive destruction of the fibres in both sciatic nerves.

† A fatal case of paralysis at St Thomas's Hospital resembled Landry's cases: it was that of a man who had been inoculated for hydrophobia, and suggested to Dr Bristowe a comparison with the paralytic form of that disease in dogs and in rabbits.

the proportion in Pellegrino-Levi's cases being twelve to four. Some cases have been ascribed to exposure to cold, or to some of the other supposed causes of myelitis described above (pp. 448–9); some have occurred during convalescence from acute diseases, as enteric fever and diphtheria, a statement that must not be taken as referring to the ordinary diphtheritic paralysis, of which the characters are altogether different.

Rarity.—Landry's paralysis is of exceedingly infrequent occurrence in England, and not a single typical case has been recorded in Guy's Hospital. Dr Wilks ('Lectures,' p. 274) relates seven cases of acute ascending paralysis, and in three of them the cord was found normal. But apart from the difficulty of accepting negative conclusions before modern histological methods were in use, the presence of anæsthesia, of vesical symptoms and of pain in all these cases, brings them under the clinical category of acute ascending diffuse myelitis. A case in a young man which ended favourably is recorded by Dr Ross, and another which proved fatal; but the latter he regards as extremely doubtful. Other authors, Bristowe, Buzzard, Gowers, Bastian, Bramwell describe the disease from French or German accounts, rather than from their own experience. The early cases of Walford ('Brit. Med. Journ.,' November, 1854), Handfield Jones (ibid. October, 1866,) and Harley ('Lancet,' October, 1868), in which last Lockhart Clarke found extensive lesions in the cord, cannot be admitted as genuine cases, and many of those published abroad are either myelitis or subacute atrophic spinal paralysis.

The fully described and probably genuine cases are certainly very few, even abroad, perhaps not thirty. The rapid course, the successive implication of legs, arms, and trunk, and finally of the bulbar nerves, including the portio dura, the absence of marked anæsthesia or pain, the absence of bedsores and rectal or vesical disturbance, the loss of knee-jerk, the absence of atrophy or spasm of the paralysed muscles and their retention of electrical contractility—make up a striking combination. The usually fatal course and negative anatomical result complete the type.

No *treatment* can be said to be indicated, but the application to the spine of ice, of heat, of the actual cautery, and of other counter-irritants, has been recommended, as well as galvanism, ergot, and other drugs.

Alcoholic paraplegia.—Under this name Wilks described a form of partial motor paralysis of the lower limbs not uncommon particularly "in ladies who have given themselves up to brandy-drinking." Pains in the legs and anæsthesia are also present.

These symptoms, with the dragging gait from dropping of the toes, the integrity of the functions of the pelvic organs, and the favourable prognosis under proper treatment, make up a recognisable clinical "disease." Dr Buzzard has suggested that symmetrical and multiple peripheral neuritis is the pathological cause of these symptoms (*vide supra*, p. 432). Dr Gowers takes the same view, and regards as minor cases of the same malady those which have been described as Alcoholic Ataxia and Pseudo-tabes potatorum. This was in fact Wilks's own opinion, for he says that sometimes the symptoms are almost confined to the legs, and resemble in character those of locomotor ataxia.

In Dr Broadbent's remarkable case of alcoholic paralysis ('Med.-Chir. Trans.,' 1884) the cord was found normal, but the nerves were not examined. He compares it with Landry's paralysis. It was in some respects unique;

but his other cases agree with Buzzard's in occurring in women, in being chiefly paraplegic, and in the muscles being tender on handling, with in one case at least sharp pains, dropped-wrist, and sphincters unaffected.

On the whole it seems probable that drink produces paraplegia occasionally by means of myelitis, and more frequently by peripheral neuritis. The latter and more common condition is recognised by the symptoms described in a previous chapter (p. 424) by the absence of pelvic symptoms, and by the frequent implication of the hands.

Syphilitic paraplegia.—That paralysis of the lower limbs may be one of the remote effects of syphilis has for several years been a well-known fact, but morbid anatomy has hitherto done very little to define the exact nature of the changes which occur in such cases. As to their relative frequency there is some discrepancy of opinion. Dr Buzzard has expressed his conviction that, in a person between twenty and forty years of age, a case of paraplegia, when not associated with Bright's disease or embolism, is (like hemiplegia under the same conditions) in nineteen cases out of twenty the result of syphilis. But this statement appears to ignore the important distinction between the pathology of the brain and that of the cord, which is represented by the common occurrence of idiopathic myelitis as compared with the infrequency of primary local encephalitis leading to softening; and probably Heubner is right when he asserts that the *lues venerea* affects the spinal cord far less often than the brain. Buzzard's limits of age appear to be too narrow, for in a case observed by Wilks the patient was a woman of fifty-three, and among the five or six other cases which have been examined in the *post-mortem* room of Guy's Hospital within the last few years, one occurred in a man aged fifty-seven, another in a woman aged forty-seven. But it is probable that syphilitic paraplegia is usually myelitis from diseased arteries. This form of paralysis has hitherto been chiefly studied at the bedside. Many years ago Sir Benjamin Brodie said that he had several times seen paraplegia stopped in its course by bichloride of mercury or by Plummer's pill. The inference has since been drawn that the cases in question were syphilitic, although there is nothing to warrant it in Brodie's brief statements concerning them. A similar conclusion has sometimes been based upon the striking results which now and then follow the administration of iodide of potassium for paraplegia, a wonderful instance of which occurred in the practice of Dr Wilks many years ago.

The frequency with which nodes are seen upon the inner surface of the skull, pushing the dura mater inwards, at one time led to the supposition that a similar affection of the bony walls of the spinal canal might occur. But this is not borne out by observation in the deadhouse. A gumma beginning in the interior of the cord is almost unknown, but it sometimes occurs in the membrane and produces paraplegia by compression.

In certain cases supposed to be examples of syphilitic paraplegia, no obvious morbid change has been discovered, or only a softened state of the cord; and we have seen that syphilis is probably an important cause of myelitis.

A man, aged twenty, was in 1877 under treatment by Mr Davies-Colley for syphilis, when he became paraplegic and was transferred to the care of Dr Wilks. He died two months later. The cord in the mid-dorsal region was flattened and soft for about an inch and a half of its length; the antero-lateral columns and the grey matter were especially affected, the latter being

of a rusty brown colour. To the naked eye there was no obvi
the pia mater. But when a piece of it, corresponding with
part, was placed on a microscopic slide and examined with a l
of the arteries were at once seen to be enormously thickened
rated. By reflected light they looked like solid, opaque, whi
by transmitted light they appeared black. We could not find
the affection was in an earlier stage, so that we might have con
Heubner's description of syphilitic arteritis in the brain. Pr
cases, hitherto regarded as syphilitic myelitis, may depend on de
supply from syphilitic affection of vessels in the spinal pia mat

Reflex paraplegia.—We have passed from myelitis as a cause
paraplegia to other more or less probable anatomical condit
ætiological varieties of paralysis. There remain cases of *functio*

It has long been suspected that a loss of function in the
causing paralysis of the lower limbs, may be an indirect res
visceral diseases. Such cases would be fairly comparable with
mentioned (p. 396), in which paresis of one arm was caused
tooth. Hammond relates the case of a girl who was brough
account of paraplegia which had suddenly developed. He
several doses of santonine, followed by castor-oil; a number of
were passed, and the paralysis disappeared in the night.

Within the last few years there has been much discussion
in which this kind of paralysis is brought about. Mr Stanl
perhaps the first to describe it ('Med.-Chir. Trans.,' 1833), v
to refer it to "irritation, propagated through the sentient
spinal cord," whence he supposed that "the impression" was
through both the motor and sentient spinal nerves to the lim
sioning an impairment both of sensation and of the power
Obviously, however, this explanation goes but a very little w
Dr Brown-Séquard published in the 'Lancet' an elaborate th
ing to which irritation of afferent nerves of a diseased organ
to set up a reflex spasm in the blood-vessels of the spinal
render it anæmic and impair its nutrition and its functions. In
year, however, Sir William Gull refuted this opinion in the 'G
Reports,' and no one now accepts it. Nor has a suggestion of J
accepted that reflex paralysis is due to "exhaustion" of th
the cord upon which fall the stimuli conveyed by the sensitive
irritated part. Thus the field remained clear for the entrance
doctrine of "inhibition," which in theory meets all the difficult
satisfactorily. Its application to paraplegia seems to have be
by Lewisson ('Reichert's Archiv,' 1869). In a series of ex
rabbits, he succeeded in paralysing the lower limbs by forci
between his fingers the kidney, or the uterus, or a large loop
The loss of power is described as lasting only as long as the
continued, or a little longer, and as always disappearing abr
nothing is easier than to refer nervous phenomena of all kinds to
influences; but this very fact makes it essential that the path
never extend the area of inhibition a hair's breadth beyond the li
a strict interpretation of physiological observations would confi
paralytic affections already referred to as being caused by disea
the paraplegia from worms in Hammond's case, were all in p

with Lewisson's experimental results, since they subsided as soon as the source of irritation was removed. Graves placed on record the case of a man who was admitted into the Richmond Hospital in 1835 with partial paraplegia of two weeks' duration, and a tight stricture, which had existed for some months. He had recently been much exposed to cold and wet, and this might have been regarded as the cause of the paralysis. But in a very few days after the first introduction of a catheter a remarkable improvement took place in his legs and in his back, where he had had much pain. In fact, the change was almost sudden; and within a month the power of the lower limbs was completely restored. It would seem that we may fairly regard this as an instance of reflex paraplegia. Cases have been recorded in women in whom the reduction of a displaced uterus has been followed by a marvellously rapid recovery from paralysis; but then it is scarcely possible to exclude the supposition of hysteria from these cases. On the other hand, the immense majority of cases which are supposed to be of reflex origin run a protracted course. It is true that the disease which is supposed to be the starting-point of the inhibitory influence is often itself permanent and incurable; but sometimes it subsides entirely, and yet the paralysis persists.

In such cases it is only reasonable to admit that there is something more than a mere reflex paraplegia; and, indeed, myelitis has sometimes been discovered after death. A particular group, in which the paralysis has appeared to be secondary to some affection of the bladder or of the urethra has been known by the distinctive name of "urinary paraplegia." Three instances of it were recorded by Gull in 1856 ('Med.-Chir. Trans.,' xxxix); in each of them a part of the spinal cord was found softened. Two similar cases have come under the observation of Leyden; the paralysis seemed to have started from a vesical affection, the result of a long-standing stricture; there was a limited inflammation of the upper portion of the lumbar enlargement with granule masses. Leyden remarks that the seat of this lesion, corresponding exactly with the spot at which the nerves of the bladder enter and leave the cord, suggests the conclusion that the morbid action had extended along their fibres. This opinion has since been supported by experiments made by Tiesler and Feinberg and Klemm, each of whom succeeded in generating an inflammation of the lower part of the spinal cord in animals by setting up neuritis of the sciatic nerves. In a dog operated on by Tiesler there was actually a collection of pus in the substance of the cord "at the point of exit of the sciatic plexus." Roesingh, however, has repeated some of these experiments with negative results, so that the question can hardly be regarded as finally settled.

Leyden ascribes most cases of reflex paraplegia to progressive ascending neuritis, and believes that the inflammatory process can be traced step by step along the whole course of the nerves.

Sir William Gull several years ago proposed a different route for the transmission of the morbid action, namely, by the veins. In a man who died of paraplegia, consecutive to a long-standing stricture, he found a small quantity of pus lying outside the sheath of the dorsal part of the cord; and one of the vertebral veins in the lumbar region was full of pus. But it is mentioned that there was a large slough over the sacrum, and, as we now know that a putrid inflammation often invades the lower end of the spinal canal from a bedsore, most probably the suppuration and the venous thrombosis arose in that way shortly before death, and were, in fact, indirect consequences of the paralysis.

There would be no difficulty in collecting from medica journals a large number of cases of supposed reflex paraple would need to be most carefully criticised.* In the 17th c Essay on "Injuries and Diseases of Nerves" Mr Bowlby has a series.

When chronic paraplegia develops itself in a person who had a stricture, or who has recently had dysentery or some tinal affection, or who has a retroflexed or prolapsed uterus, forget that this may be a mere coincidence. Brown-Séquard down a series of fifteen criteria, by which he thought that a refl might be distinguished from one due to an organic lesion in th now that we know that myelitis is present in most of the cases to be of reflex origin, these criteria must be set aside, even if ex not shown that no reliance could be placed on them. The exclude the possibility that the relation between the primary di paralysis is accidental is to show that the cases in question are for mere coincidence. But has this yet been shown? If not congestion of the cord, reflex paraplegia must be at least a rare malady.

Hysterical Paraplegia.—It is a well-recognised fact that not infrequent cause of paraplegia; the proof being that young have previously suffered, or are actually suffering, from oth symptoms are apt to be affected with paralysis of the legs, wh after a time, or sometimes suddenly, under the influence of so moral shock. To define as accurately as possible the characte affection must evidently be of great importance in reference and treatment; for the diagnosis cannot be taken for granted u fact that the patient has hysteria, and (on the other hand) affe hysterical are occasionally met with in persons who do not pr indications of that disease.†

Mere malingering is not difficult to detect, but hysterical p very different thing. Apart from the probabilities afforded by

* In the Guy's Hospital Library copy of the 'Medico-Chirurgical T 1833, containing Mr Stanley's paper, there is a pencil-note by Dr Wilks, t the majority of his cases were wrongly interpreted, and were really exampl inflammatory softening of the cord, attended with secondary cystitis and n are, indeed, two cases to which this remark does not apply: one is th admitted into St Bartholomew's Hospital for retention of urine (attribu gonorrhœa, the discharge of which he had stopped by injections), who be and died in about a fortnight; the other, of a man who was getting well when he was seized with paralysis extending up to the umbilicus, and fell bed sixteen hours afterwards. But we shall find cases in which septicæmi fatal cerebral symptoms for which no adequate explanation could be found and it seems not unlikely that the cases just quoted were really of that nat merely reflex, or due to inhibition of the spinal centres.

† There is a remarkable want of agreement among writers as to the crite paraplegia. Radcliffe and Bastian say that the paralysis is usually incomp completeness is, in a doubtful case, an argument for paraplegia being Duchenne attached much importance to the presence of a diminution of el without loss of electro-contractility; but Reynolds has related two cases sensibility, sensibility to electricity, and electro-contractility were all perfec that although each of these patients could raise her legs from the bed, ye made to attempt to walk, no amount of help could prevent her from tumbling down to within a few inches of the ground, and then she would without assistance. Even as regards micturition, Radcliffe states that " rectum are little, if at all, under control; less so, as a rule, than in common

sex of the patient, the following points are of service:—There is usually retention but seldom or never incontinence of urine; obstinate constipation but never incontinence of fæces; and bed-sores do not form. The motor palsy, though absolute at certain times, is at others slight; sensory palsy, patches of anæsthesia, hyperæsthesia and analgesia are much more marked than in ordinary paraplegia, as much as in total transverse lesions with pelvic symptoms. Analgesia without loss of touch or sense of temperature, and anæsthesia without loss of movement are almost diagnostic of hysteria. Electro-sensibility is often small or absent, but the muscles respond normally to galvanic or faradic stimuli. The paralysed limbs are cold but do not waste. Rigidity and contraction, most frequently flexion, are frequent and early symptoms, but they are completely removed under chloroform and during sleep. The knee-jerk is sometimes absent, sometimes exaggerated.

Wilks remarks that hysterical girls remain plump in spite of their being affected with paralysis. Sir William Gull used to point out the coldness and pallor of the legs in such patients, as contrasting with their condition in cases of organic disease of the cord.

We ought to be extremely careful in diagnosing paraplegia as hysterical, since neurotic girls are not less liable than other people to myelitis, caries of the spine, and other causes of organic paraplegia.

Dr Reynolds has described a closely allied functional paralysis, which he called paraplegia dependent on an idea ('Brit. Med. Journ.,' Nov., 1869).

The *treatment* of hysterical paraplegia is that of hysteria, and electricity should only be used, if at all, for its effect upon the mind.

NEURASTHENIA SPINALIS.—"*Spinal weakness.*"—Among the patients who seek medical advice, believing that they are suffering from spinal disease, there are some—chiefly youths and men not far advanced in adult life—whose principal complaint is of muscular fatigue and weakness. If they attempt to walk far, they experience aching pains or stiffness in their limbs. When they have to stand for more than a short time, their legs tremble and seem to give way under them. They feel tired and weary all day long, even before they get out of bed in the morning. "Spinal Neurasthenia," as a special name for these cases, was originally proposed by Drs Beard and Rockwell in 1871, and is accepted by Erb, Ross, and other systematic writers. The exciting causes appear generally to be either over-exertion of body or mind (especially if carried on during the hours that ought to have been devoted to sleep), or the various forms of sexual excess. There is irritable weakness of the generative organs, and sometimes a little dribbling of the urine after micturition. In some cases dragging or tearing pains in the limbs were complained of; but generally these were not severe. Very often there was a peculiar pain in the back, seated apparently in the muscles, increased by movements of the spine or of the scapulæ. Sometimes local tenderness of certain spinous processes was present, exactly as in the affection known as rachialgia or *spinal irritation;* it may be said that the two neuroses are combined in the same patient. Often there is mental disturbance indicated by sleeplessness, timidity, and depression of spirits. In fact, the condition is that long recognised as a form of sexual hypochondriasis, or, as it used to be called, tabes dorsalis.*

* The cases cited in a work by Surgeon-Major Neale, published under this title in the year 1806, are many of them of this character.

It is supposed by Erb that the state of the nervous el spinal centres in such cases is in fact the same as in the heal exhausted by the discharge of its functions, and that the dif natural period of rest failing to restore them to vigour and a view seems reasonable enough.

The *diagnosis* from myelitis and from other serious spinal be based mainly upon the absence of objective symptoms of a of the cord, in contrast with the vehemence with which the plains of his subjective sensations.

Spinal neurasthenia sometimes develops itself in the co days, but much more frequently its advent is gradual and s reach such an intensity as to compel the sufferer to give up l and to renounce all society. It is often obstinate, lasting for or for years. Relapses sometimes occur. Whether it ever passes on into any organic affection is doubtful.

Treatment should be directed entirely to the general hea from the spinal symptoms. Cold sponging, exercise out of nence from liquor and from sexual indulgence, aided by the steel, strychnia, or cod-liver oil are usually successful. Galv of decided benefit.

RACHIALGIA. "*Spinal irritation.*"—In 1828 Dr Thomas B gow, drew attention to an affection attended with pain and ten or more of the vertebræ, and termed it *spinal irritation*. He by Mr Teale, of Leeds (1829), by the brothers William and of Limerick (1834), and by Stilling, of Cassel (1840), the devoted a volume of 540 pages to the subject. All these ob very wide scope to the definition. They detected tenderne over certain spinous processes in persons suffering from var and other affections, and they maintained that in all such c state of the spine was really the fundamental disease. They their definition, so as to include transitory paralytic affections of other neuroses. In this they were no doubt influenced which they had adopted, for it would obviously be difficu from "spinal irritation" almost any "functional" disorder nervous centres from tetanus to pleurodynia.

It is not surprising that these views met with much oppo were criticised in trenchant style, but very justly, by Romb have never met with general acceptance in this country. Ollivier maintained that "spinal irritation" was due to the the cord (p. 453). More recently Hammond has asserted tha condition is spinal anæmia (p. 451). The boundary lines b irritation and other affections have been repeatedly shifte observers have ignored it altogether. This is to be regretted, undoubtedly some cases which naturally fall under this hea have hitherto found no other place in the nosology. It is clinical importance to recognise an independent neurosis, cha pain and tenderness in the back, but unattended with any organic lesion of the cord, or of the vertebræ. The most of "spinal irritation," may be regarded as a form of neura the posterior branches of the spinal nerves, and perhaps distributed to the meninges of the cord. It is true that the

and of Van der Kolk (p. 386), would explain how pain may be referred to the cutaneous nerves of the back, even though its starting-point is within the spinal cord; and such a view of "spinal irritation" is undoubtedly supported by the occasional transference of impressions from the posterior to the anterior branches of the nerves in cases of this kind. After all, this question of its centric or excentric seat is not peculiar to rachialgia, but concerns every other form of neuralgia likewise.

But even if spinal irritation is a neuralgia, it is most usefully considered in this place, on account of the importance of the diagnosis between it and the more grave diseases of the vertebræ and of the cord—just as it is convenient to classify pleurodynia with affections of the chest, and gastralgia with those of the stomach. Considering the abuse of the term "spinal irritation," it is better to denote this condition by the word *Rachialgia*, which was long ago employed by Joseph Frank, and corresponds with those applied to other local neuralgic affections.

Symptoms.—The severity of the pain varies indefinitely in different cases. Sometimes there is no spontaneous pain at all; but by pressing upon the different spinous processes we may find that some of them are tender; the patient shrinks or complains that we are hurting him, but he may hitherto have had no idea that anything was the matter with his spine. Great stress was laid on cases of this kind by those who pushed the theory of "spinal irritation" furthest. They were in the habit of directing their treatment mainly to the supposed spinal affection, and applied leeches, blisters, or tartar-emetic ointment over the vertebræ. Romberg, however, tells us that very little was effected by these measures, which we can well believe.

In other cases there is a dull aching sensation in the affected part of the spine, or even severe pain. Its development is usually gradual. At first it may be felt only after great fatigue or excitement; but, as time passes, slighter causes excite it and it is less ready to subside, until at last it becomes constant. It is almost always increased by muscular efforts and by movements of the vertebræ, so that the patient is unable to walk far, or to stand upright for more than a short time; even sitting at the piano, the writing desk, or the sewing machine, may be too painful to be borne.

Sometimes the best way of bringing out the increased sensitiveness of the affected nerves is to pass one's fingers along the spine, so as to press upon the vertebræ in succession; sometimes it is more manifest when a sponge wrung out of hot water is drawn down the back. To the patient this seems to scald at the tender spots, while he experiences no discomfort elsewhere.

There is often a close anatomical relation between the seat of rachialgia and that of any other neuralgia which happens to be present in the same case—the one corresponding with the posterior, the other with the anterior main branch of a spinal nerve. This statement is, indeed, almost identical with one which used to be insisted on by Trousseau; namely, that a "*point apophysaire*" is discoverable in most instances of neuralgia. Pressure on the tender vertebra will often bring out or increase the pain in any other part that happens to have its nerves in an irritable condition.

Thus one of the cases related by Dr and Mr Griffin (at p. 19 of their work) is that of a girl who complained of headache and pains in all parts of her body. Her whole spinal column was acutely tender. Pressure upon the

first or second cervical vertebra caused a pain which shot fo occiput to the brow; a little further down, it excited pain over the lowest cervical spine, at the spot where the trac the sternum; and still lower, at the middle of the sternu cartilage, and the pubic region successively. This certainly any direct mechanical impression upon the cord; for whe made behind the trochanter, pain was felt at the iliac crest, the thigh, and even in the opposite hip; while pressure up knee set up pains in the shins and toes.

In some cases there is a fixed spot in the front of the pain is always referred when any one of several tend pressed upon. Thus another of Dr Griffin's patients had g of all the dorsal and lumbar, but not of the cervical sp Pressure on the upper dorsal vertebræ caused pain at th sternum; from the third or fourth dorsal down to the sa pain, not in the corresponding points as usual, but at the en Pain at this spot was even brought on by pressure behind upon the muscles of the thigh, or over one knee-joint, and the same pain if she chanced to tread on uneven ground, or beneath her feet in walking. To ascertain whether the sev dorsal vertebræ were, as usual, more affected than other pa firm pressure was made upon them. The result was tha tumbled forwards insensible, and would have struck her floor had not some one caught her. Such an occurrence mi almost incredible; but the same observers have placed s record.

Another of their patients was a lady who complained of but who "had no conception that her spine was at all affecte second cervical vertebra was touched she sprang up, as been driven through the cord, and then fell in a state insensibility. Out of this stupor she twice started up in and as often dropped back powerless, her countenance evin terror and agitation. As soon as she could speak, she sai felt a numbness and sensation as of pins and needles in all ensiform cartilage. She would on no account permit her ne again.

A fourth instance was that of a young gentleman, who d as suffering from a chronic liver complaint. Pressure u column was excessively disagreeable to him. When the fi one of the dorsal vertebræ he grew pale and terrified, saying thrill through every nerve in his frame. He had an un about the part for the remainder of the day, and shuddere allowing the pressure to be repeated. After a few weeks was tried again, and with precisely the same results.

A fifth case was that of a boy, aged twelve, who fell forw as if he had been shot, as soon as slight pressure was made u lumbar spine.

Phenomena somewhat similar, though less marked in uncommon. They undoubtedly lend support to the view t rachialgia is in the cord itself rather than in the nerves. A a case in which pressure on one spot, over the lowest ce caused exquisite pain, a sensation of extreme nausea, and

the pulse at the right wrist, that on the left side remaining unaltered. The patient, a young lady, was also seen by Dr Walshe and Dr Reynolds. In the case of a child, brought to Dr Frederick Taylor, at Guy's Hospital, it was repeatedly noticed that pressure upon the seventh cervical vertebra at once gave rise to a marked pallor of the left side of the face, which lasted a few minutes.

Ætiology.—Dr Radcliffe suggested that the cause of rachialgia (or, as he terms it, "spinal irritation") is often a strain of the back or a blow, which may have been forgotten by the patient. This supposition is confirmed by the fact that slight railway accidents so often give rise to it. The so-called "Railway-spine" is, in fact, in the great majority of cases an affection of this kind. Anstie's patient, just referred to, had received a very slight contusion in a collision. Her sister, who was severely injured at the same time, nursed her assiduously for three or four months, and then began to be seriously ill herself. Many observers think that no reliance can be placed on the statements of persons who have met with such accidents, so far as their subjective symptoms are concerned. But the author saw several cases in which there was abundant collateral proof of good faith.

A general "nervous susceptibility" certainly plays an important part in the ætiology of the complaint. It is far more common in women than in men, and in persons between fifteen and thirty years of age, than in those at earlier or later periods of life. An inherited "neuropathic tendency" predisposes to it. Like other neuralgiæ, it often affects women who at the same time are obviously suffering from hysteria; and thus it may be associated with any of the varied symptoms of that morbid state.

Among other causes to which rachialgia has been attributed are over-fatigue, exhaustion by night-watching, sexual excesses, onanism, violent mental emotions, and insufficient food; but probably none of these are more than predisposing causes.

Prognosis.—Rachialgia may develop into marked hysteria in women, or into neurasthenia spinalis in men, but the usual course of the affection is towards recovery. Relapses, however, are common, and often the subsidence of pain in a particular spot in the back is followed by the appearance of neuralgia elsewhere, or of some different neurosis.

Treatment.—A most important point to be determined is whether or not rest in the horizontal posture should be insisted on. Some of the patients whom the late Mr Hilton used to keep lying on their backs for months together, with sandbags to prevent any movements of the spine, were (as Dr Fagge believed) sufferers from rachialgia rather than from actual spinal disease; yet undoubtedly good results were obtained. Mr Teale says that he succeeded in curing several persons belonging to the poorer classes while they were still pursuing their laborious vocations; and in many cases the general nervous state renders it exceedingly desirable that the patient should have fresh air and change of scene, and should even be encouraged to take moderate exercise, short of fatigue. An abundant supply of good food is of great importance. Dr Radcliffe advised a somewhat bold use of alcoholic drinks as a cardinal point in the treatment; but Dr Anstie would only allow them in great moderation, and only with the meals. This is the wiser course, or we may have not only rachialgia but a worse disease to deal with. If "spinal irritation" is only a combination of hysteria and neuralgia, it is food, not narcotics, which are useful. Quinine, the tincture of steel, strychnia, and cod-liver oil are each of them valuable

adjuvants. The application of blisters to the spine is reco
some modern authors, and older writers speak no less favourab
and of cupping. These measures are now out of fashion; bu
severe and obstinate case which arose out of the Thorpe rail
and which the author saw with Mr Erichsen and with Mr
Norwich, nothing gave so much relief as the repeated applicati
at intervals of a few weeks, and especially at the catamenial p
patient was stout and florid. Other applications that hav
proved useful are turpentine liniment and unguentum veratr
of hot sand may be placed along the spine, or a galvanic cu
through it in the manner directed for neuralgic affections in ge

HEMIPARAPLEGIA.—There is a curious and rare kind of para
a lesion which is limited to one lateral half of the cord, but
half completely at a certain level. As might be anticipated, th
power in the half of the body which is on the same side as th
the cord, and the upper limit of the paralysis varies with the d
the highest nerves coming off from the part of the cord belo
the disease. Such a condition may conveniently be terme
plegia, whether it is limited to the leg or involves the corres
as well. What could not have been foreseen, until Brown-Séq
demonstrated the fact in animals by dividing one half of the
is that anæsthesia is present, not on the same side as the diseas
opposite side. That half of the body which retains its moto
its sensibility, while the paralysed half has its sensory function
or exalted. The explanation of the crossed anæsthesia is t
the fibres belonging to each sensory nerve-root decussate
stance of the spinal cord itself, immediately above their ent
least before they reach the level of the decussation of the
in the pyramids. This applies equally to the fibres which
sorts of impressions,—whether of touch, or pain, or heat an
with the curious exception that the fibres belonging to t
sense run upward without crossing. Thus, there is said to
muscular sense, and with it, of electro-muscular sensibility, on t
and not on the anæsthetic side of the body. Why there shoul
hyperæsthesia of the skin on the paralysed side,—the susc
tactile and to painful impressions and to change of temperatu
increased,—is not so clear. The inflammatory action which de
in the neighbourhood of the lesion may render the fibres undu
or there may be a suppression of some normally controlling inf

Thus it would appear that no disease of the spinal cord pro
rise to paralysis and anæsthesia limited to one and the same
body. If a patient is found to have one of his lower limbs,
affected in this way, we are justified in concluding that the
concern the corresponding half of the nerve-roots which form
equina—unless, indeed, it is seated above the decussation of t
in the opposite half of the encephalon. In other words,
peripheral neuritis or a cerebral lesion.

On the other hand, it must not be supposed that every affe
side of the spinal cord necessarily causes paralysis of the sa
anæsthesia of the opposite side of the body. This effect is ob
when the abolition of function in that half of the cord is compl

so. All morbid changes in the nervous structures produce loss of motor power more constantly than loss of sensation, and unilateral lesions of the cord offer no exception to this rule. It is quite possible for such a lesion to give rise to complete paralysis of one lower limb, or of the arm and leg on one side of the body, without there being any anæsthesia of the limbs on the opposite side. Such cases were formerly known under the name of "spinal hemiplegia." The explanation of them is that the disease, while it is confined to one half of the cord, nevertheless leaves a part of that half functionally active. The best marked cases are those which will be hereafter discussed as essential spinal paralysis in infants and in adults, where the anterior cornua are the seat of the lesion.

The vaso-motor nerves are said to be affected on that side which is the seat of the lesion, especially when this has occurred suddenly or developed itself rapidly. The temperature of the paralysed limb or limbs is at first higher than that of the corresponding parts by a difference amounting to 1° or 2° Fahrenheit or even more. After a time, however, it becomes normal, and sometimes falls to a still lower level.

With regard to the state of the reflex excitability of the lower spinal centres in cases of hemiparaplegia, there is still some uncertainty. On the paralysed side it has in some cases been increased, in others it has been diminished; on the anæsthetic side it has generally appeared to be normal, but occasionally it has been exalted. Erb says that the bladder and rectum have generally been paralysed—always when there has been a sudden traumatic lesion—with either complete retention or complete incontinence of urine, and involuntary passage of fæces. This appears to lend powerful support to the view that the paralysis of these parts in cases of ordinary paraplegia, due to a bilateral lesion limited to the upper part of the cord, depends on an inhibitory influence transmitted downwards from the diseased parts to the healthy centres below. An analogous fact, which has now been noticed in several cases, is that the muscles on the paralysed side in hemiparaplegia sometimes have their faradic contractility lowered in a marked degree; they may also undergo rapid wasting.

Hemiparaplegia may be due to many different *causes*, but not to so many as those which may produce paralysis on both sides of the body alike; and some of the rare lesions of the cord are most apt to give rise to it. Thus it has been observed in patients who have been stabbed in the back by a knife or dagger. It seems strange that a chance wound should make a section of one half of the cord with the accuracy of an incision performed by an experimental physiologist; but the shape and size of the spaces between the arches of the vertebræ are possibly such as to prevent a cutting instrument from passing across the median line within the spinal canal. Now and then a fracture or a dislocation of the spine has been attended with hemiparaplegia, and perhaps an effusion of blood into the membranes on one side may cause it. A tumour outside the cord, compressing one half of it, has more than once caused paraplegia of one leg. In other cases this form of paralysis has been due to a lesion limited to the interior of the cord on one side: an effusion of blood, a patch of sclerosis, or of acute focal myelitis, an intrachordal tumour, or a gumma.

Some of these various unilateral lesions are more apt than others to affect a considerable length of the cord, and at the same time to involve the roots of several spinal nerves. This leads to the development in many cases of hemiparaplegia of a fresh set of symptoms due to interference with nerve-roots.

Thus there is commonly an anæsthetic half-zone of greate passing round the paralysed half of the body from back dividing the hyperæsthetic part of the surface below from t above; and the upper edge of this anæsthetic space is sai present a narrow hyperæsthetic border. The explanation i nerves of the region deprived of sensation have had their roo the disease; those of the region which is over-sensitive have r roots irritated. The other (or anæsthetic) half of the body has a narrow hyperæsthetic half-zone, limiting the anæsthe due to irritation of fibres which have just decussated at the up lesion in the cord. In some cases the patient experiences sense of constriction, or severe burning or shooting pains, rou a level corresponding with that of the nerves whose roots are disease, and such sensations may be limited to one half of th both sides alike. We shall presently see that exact coun these symptoms are met with in certain forms of paraplegia on slow compression of the cord.

The *course* taken by hemiparaplegia varies in different to the nature of the disease that gives rise to it. It very stationary. Most commonly it soon undergoes conversion paraplegia, as the result of the development of myelitis, w whole thickness of the cord around the original lesion. fatally, but sometimes, according to Erb, it subsides and allow of a unilateral lesion to reappear. These may then persist fo change, and in certain cases they have been known to termin According to Brown-Séquard, the power of motion is then and more completely than that of sensation. If this is th opposition to what is observed in all other affections, whethe or of nerve-trunks.

The second group of affections causing Paraplegia (cf. p those in which the primary lesion is *extrinsic*, or outside the co subjecting it to *slow compression*, so as first to produce pain with the posterior roots of the nerves, then to excite sec with softening, and finally to destroy the cord completel affected.

Compression-Paraplegia.—Ollivier and Cruveilhier separate form of paraplegia that which is produced by t pression of the cord." The importance of thus grouping t affections of the parts which surround and support the sp not to have been recognised by the writers who followe recently, several observers have worked out the idea in others Charcot, who, however, includes in his descriptio tubercles lying in the interior of the cord, although, as he some of the most characteristic phenomena are absent in suc

Causes.—In the first place it is to be remarked that some spine never cause paraplegia. Thus the cord seems always to sion in cases of lateral curvature (or *scoliosis*, as it is often c extreme may be the deformity. Leyden, indeed, alludes to which the patient was unable to stand or walk for more tha of time, but such an effect is quite exceptional. Whethe

canal is ever narrowed in cases of *osteo-arthritis* is doubtful. In 1838 Aston Key related in the third volume of the 'Guy's Hospital Reports' two cases of paraplegia in each of which Wilkinson King—a pathologist of deserved reputation—found an intervertebral substance projecting backwards with raised lips upon the edges of the two adjacent vertebræ, and in one instance with an ossified posterior common ligament bridging over the space between them. It was taken for granted that this was the cause of the paralysis, but this may perhaps be doubted. Gowers mentions two cases of intravertebral *exostosis* compressing the cord. Syphilitic *nodes* seem never to grow from the bodies or arches of the vertebra inwards, so as to interfere with the cord.

1. *Caries of the spine. Pott's disease.*—The most frequent, and therefore by far the most important, of all the affections that are really capable of giving rise to a "compression-paraplegia," is that which, from the kind of deformity produced by it, is in this country commonly known as "angular curvature," but which on the Continent is universally called after one of the greatest English surgeons of the last century, Percival Pott, of St Bartholomew's Hospital. It consists in the destruction by caries, with or without necrosis, of the body or bodies of one or more vertebræ, which then fall together beneath the weight of the head and upper part of the trunk. The necessary result is a displacement of the corresponding arches and spinous processes, which become bent into a sharp angle or rounded curve, according to the number of the bones which are diseased.

Opinions differ with regard to the mode of commencement of this morbid process. German pathologists agree in stating that it begins in the bodies of the vertebræ, the discs escaping or being implicated only at a late period; and undoubtedly one may see vertebræ with caseous masses in their interior, or even irregular cavities, which nowhere touch the discs. But, as Wilks long ago pointed out, there is in some cases a source of fallacy in the fact that when a disc is completely destroyed, the adjacent vertebræ often lose each about half of its substance, and the remaining halves, coming together, look exactly like the fragments of a single bone ulcerated through by the disease. The author has repeatedly found intervertebral discs above and below the main seat of mischief presenting early changes of such a kind as to convince him that in the particular case under observation they, rather than the bones, were primarily affected. Thus, in an instance recorded by Sir William Gull ('Guy's Hosp. Rep.,' 1856, p. 179), death occurred from an affection of the cord at a time when the only change was softening of three of the discs, with the formation of a cheesy substance in the middle one and a little "absorption" limited to the adjacent part of the bone.

Another question formerly debated, whether caries of the vertebræ is to be regarded as "scrofulous," is now decided—partly by the presence of tubercular lesions elsewhere, partly by detection of the characteristic bacilli of Koch. Cases of tubercular pyelitis or of Addison's disease are now and then accompanied by an affection of the vertebræ immediately adjacent; and a similar affection occurs in conjunction with pulmonary phthisis, or tubercular disease of the testis, or disease of other bones or joints. Like tubercular lesions of joints, caries of the spine can, however, often be traced to accidental injuries.

In most instances of permanently cured angular curvature with ankylosis, the active stage of the disease was passed through in childhood. Of sixteen cases, all causing fatal paraplegia, in fifteen the patients were adults, four between twenty and thirty years of age, three between thirty-one and forty,

seven between forty-one and fifty, and one fifty-six. The only ankylosis existed was one in which the spinal disease beg patient was six years old, and he died at thirty-two.

Considering how great is the deformity in many of these c much it alters the relations of the arches of the vertebræ to one could not be surprised if the displaced bones often co cord directly. That this does sometimes occur appears clea of Brown-Séquard's, in which paraplegia which had set in removed in twenty-five hours by extension of the spine. But logical museum contains specimens which show that the generally remains of its full width, however much its dire altered. Moreover, as Charcot points out, paralysis often oc of vertebral caries in which there is no curvature at all; w cases, in which curvature exists, the patient regains the use although the state of the bones remains unaltered. The im of pressure on the cord when there is caries of the spine is, as in 1856, a mass of cheesy *débris*, which collects between the affe and the dura mater, having, perhaps, been extruded from fibro-cartilages or from the carious bones, as the result of dest posterior common ligament. As Michaud observed, the ou the dura mater become in their turn converted into a thick, yel mass.

2. *Malignant disease of the spine.*—This is the only other f of extrinsic paraplegia. It assumes a variety of forms. is secondary to carcinoma of the breast, or to sarcoma occ lymph-glands of the neck or loins or in one of the long bones of the œsophagus or colon, the uterus or testicle. The nature is sufficiently obvious if there has been a primary affection in parts, especially if a surgical operation has already been perf is otherwise when the growth is seated internally, as, for in mediastinum. Sometimes the vertebræ become affected with mal by direct extension, as from a cancer of the kidney. Sometin lesion is itself a primary new growth. In these cases it is gener of one kind or other; and not infrequently it affects simultaneo of vertebræ in different regions, as well as other bones, such a limbs, the ossa innominata, or the skull. Thus a careful sear may lead to the discovery of a tumour in some distant part and so may clear up a case that would otherwise have remain obscure.

Sometimes there is a distinct projection of one or more cesses, or a mass of the growth can be felt within the sub erector-spinæ muscle. Sometimes a tumour in connection wit the spinal column is discovered when deep pressure is mad cervical vertebræ are diseased, manipulation of the neck m enlargement on one side corresponding with the transverse pr in the great majority of cases one can feel nothing abnormal lies entirely within the spinal canal, except in so far as it bodies or laminæ of the vertebræ.

Of seventeen cases of malignant disease of the spine, colle records of *post-mortem* examinations at Guy's Hospital, tw males, five in females. The patients were of all ages, fr sixty-eight.

In one case in Philip Ward a correct diagnosis was possible, from the age of the patient excluding caries, while the severe pain and its increase on pressure of the spine downwards pointed to the vertebræ. It was confirmed before death by the detection of a tumour in the abdomen, which proved to be a cancerous gland.

In another case, occurring in a man aged 50, the paralysis was very slight, and the pain and other symptoms subsided so much after rest in bed that the patient was allowed to get up. The same day he was attacked with renewed pain, and paraplegia became complete. Death speedily followed, and we found that while secondary cancer of the vertebræ had compressed the cord, the weight of his body in walking had crushed the bones together, and destroyed that segment.

In two of the writer's cases, the primary growth was in the œsophagus. In thirteen other cases at Guy's Hospital it was in the vertebræ in five, in the bladder and prostate in two, in the breast, uterus, colon, or adrenal in the remainder.

3. *Erosion of the vertebræ by aneurysm.*—Common as it is for an aneurysm of the aorta to eat away the bodies of the vertebræ with which it comes into contact, it very rarely penetrates the spinal canal so as to interfere with the cord. We have in Guy's museum specimens from two such cases, in each of which paraplegia developed itself at a period long after the discovery of a pulsating tumour in the back. A third remarkable instance of this kind occurred in 1871. A man, aged thirty, was admitted into the hospital for paraplegia, which had begun three months previously. He had first complained of pain in the shoulders, then his left leg became weak and numb, and afterwards his right leg, and he experienced a pain as though the abdomen were constricted by a cord. He died without our suspecting of the real nature of his disease. When the erector spinæ was cut into, a large mass of laminated clot was found in its substance on the left side. This belonged to an aneurysm of the descending aortic arch, which had destroyed several ribs, and laid open the spinal canal for a space two inches in length. Some of the clot adhered to the outer surface of the dura mater; the cord itself was flattened, white, and very soft.

4. *Erosion of the vertebræ by a hydatid.*—This also is extremely rare. A striking instance is recorded by Cruveilhier. A large echinococcus lay behind the vertebræ, and filled the groove on each side of the spine beneath the lumbar muscles, so as to form two elongated pouches, which were connected together by a narrow neck. A somewhat similar case occurred to Dr Moxon in 1871, a few months before the case of aneurysm just referred to. The parasite was "multilocular," budding externally. It formed a large elastic swelling on the left side of the spine, and made its way into the canal through the second and third lumbar vertebræ. It compressed the cord, but did not penetrate the dura mater. The patient, a woman of fifty-eight, had been paraplegic for six weeks.

5. *Meningeal tumour.*—New growths of various kinds occasionally form in connection with the spinal membranes, and may press on the cord so as to produce paraplegia. Sometimes a lipoma or an enchondroma is formed in the connective tissue outside the dura mater of the cord. More frequently, one of the spaces within the sheath is the seat of the affection. According to Charcot, tumours are particularly apt to grow from the inner face of the dura mater—generally sarcoma or psammoma. New growths

of the spinal membranes, although rare, are much less so th
begin in the cord itself.

Sir William Gull described three cases of this kind in
paraplegia in the 'Guy's Reports' for 1856: one (? a myxo
the inner surface of the dura mater at the first dorsal vertebr
a sarcoma, had the same origin a little lower down; the thi
gumma) grew from the pia mater in the lower dorsal region.

In one more recent case at Guy's Hospital, a tumour of
loped fibrous tissue lay close to the foramen magnum and e
wards for more than two inches, so as to press upon the ba
on the left side. In another case a soft, granular, redd
smooth and lobulated on the surface, lay loosely attached bet
noid membrane and the pia mater, in the dorsal region.
inch and a quarter in length, and consisted partly of fib
spindle-cell tissue.

6. *Meningeal gumma.*—This affection also seems to be
more so than tumour. Virchow has related a case in which
in the lower cervical region was increased to three times its no
and was bound down to the bodies of the fifth and sixth ce
by a large quantity of firm connective tissue, which was believ
in a gumma. Wilks once found a hard, irregular, yellow mass
of an inch long, and probably syphilitic, lying on the right s
within its sheath, and adherent to the pia mater and to the po
the spinal nerves, which were compressed by it. In a case
('Guy's Hosp. Rep.,' 1871) there were a number of brown
patches, from the size of a barleycorn to that of a pea, with
centres, penetrating into the substance of the cord from
In one described by Heubner, in 'Ziemssen's Cyclopædia,' a
extended from the floor of the fourth ventricle into the bulb
one twelfth of an inch; while in the cervical region the
the other membranes behind the cord were pressed together
mass, which was firmly adherent both to the arch of the a
posterior columns of the cord.

Symptoms of compression-paraplegia.—At the bedside we re
condary paralysis, and distinguish it from primary affections of
not so much by peculiarities in its proper symptoms as by th
are accompanied, and in most cases preceded, by symptoms d
ence with the roots of the nerves coming from the cord at
the level of the lesion. By Charcot these are termed "extrin
while he gives the name of "intrinsic" symptoms to the loss
in parts lower down, to the anæsthesia, and to the other effe
upon the cord itself.* Erb describes the former as belongi
stage," the latter to a "second stage" of the disease.

The statement that the earlier phenomena are due to som
nerves having their roots directly involved in the lesion, i
speculative opinion. They have been observed on dissection
and greatly swollen, even when not showing any mark
change; while in advanced cases they have been found transp
and atrophied, with their fibres in a state of fatty degenerati

* The terms extrinsic and intrinsic are also applied to denote lesions
and those which affect it from outside, respectively—intra-medullary an
as they are called by some writers, with reference to the medulla spinalis.

Chief among the early symptoms is *pain;* and few points in clinical medicine are more important than the fact that this is referred by the patient, not to the seat of mischief, but chiefly or solely to those parts to which the affected nerves are distributed. Thus, there is always danger of mistaking cases of spinal disease for various other affections; now for occipital or brachial tic, then for pleurodynia, and again for gastrodynia, for colic, or for sciatica. Very often the pain appears to be fixed in a single spot, or to occupy only a very small part of the whole surface supplied by a single nerve. In other cases it shoots through all the main trunks belonging to a limb. Charcot lays stress on its burning character and on the absence of *points douloureux*, as distinguishing it from (idiopathic) neuralgia; but if we believe with Anstie that the *points* are to be detected only in nerves which have already been the seat of pain for a considerable length of time, the distinction is not of much service.

Associated with the pain there is often an extreme degree of hyperæsthesia. The patient may be unable to bear even the slightest touch without crying out, while every movement is excessively painful. On the other hand, there is sometimes impairment of sensibility or actual anæsthesia over a more or less extensive part of the surface to which the affected nerves are supplied. The muscles which receive branches from them may show tonic or clonic spasms, or become paralysed and even atrophied, with loss of faradic contractility and inability to respond to reflex stimuli. An eruption of herpes zoster has now and then been observed in the course of some of the nerves which are involved in the disease.

It is to be observed that these pains are symptoms of compression-paraplegia only indirectly; they depend on the nerve-roots or branches being pressed upon, and may occur whenever spinal nerves or their roots are involved in disease, though the cord may to the last remain intact. Thus lateral curvature of the spine, which probably never causes paralysis, is frequently accompanied by a fixed pain in one or more of the ribs or intercostal spaces, which seems to be due to pressure upon nerves as they are passing through the intervertebral foramina. In the following remarkable case of medullary sarcoma of the vertebræ there was at no time any well-marked paralysis. The patient was an errand-boy, aged sixteen, who, five months before his death, began to experience pain first in the loins, then in the shoulders, and then in all his limbs. His sufferings became almost unbearable. The whole surface of the body was excessively tender, but especially the lower part of the back. The pain was constant, but it varied in position. There was numbness and a sensation of tingling in each hand; this was first noticed in the fingers supplied by the ulnar nerve on either side. He became wasted to the most extreme degree. The only way in which he got any ease was by lying flat on his back, with his legs drawn up. Every movement of his neck, and of any part below it, caused him severe pain. One day he became insensible and had a series of epileptiform seizures, in one of which he died. A mass of white medullary new growth (with microscopical characters, such as are now known to belong to the sarcomata) occupied the lumbar glands, and spread from them to the intervertebral discs, eating also into the lumbar vertebræ themselves. It passed up in front of the spine into the neck, where it involved part of the brachial plexus on each side. It nowhere penetrated into the vertebral canal or implicated the membranes of the cord.

There seems to be no doubt that pain is more marked as an early symptom

in cases of malignant disease of the spine than in those of compression-paraplegia.

Cruveilhier long ago brought together under the name *douloureuse* certain cases attended with intense lancinating pain of the sciatic and lumbar plexuses, and with paralysis of t branches. Recent writers have remarked that a large majorit in question are instances of malignant disease of the spine, roots of the nerves for the lower limbs in the cauda equina for this distribution of symptoms seems to be that wherea lumbar and lowest dorsal vertebræ frequently become cance not often affected with caries.

On the other hand, in fourteen consecutive cases of p to Pott's disease of the vertebræ, collected from our *post-m* at Guy's Hospital, the caries did not once occupy this the spine. A few other cases in which it did occupy this without paralysis. Thus in one instance the third and f vertebræ were found "extensively diseased," and in anothe and twelfth dorsal vertebræ had entirely disappeared, so that or the spine a large space was seen in front, in which the cord was exposed; but in each case the disease had been during life, for the patient had been kept in bed for a consid some other malady, and this no doubt had enabled the spinal being compressed. In the report of the second case it is e that repeated questions failed to elicit any complaint of pain, back or elsewhere.

Pain in the back itself—rachialgia, already described as although not infrequently present as an early symptom of com plegia, is far less constant than one might have expected. different forms. Certain of the spinous processes may be tend or over-sensitive to a slight blow or jar, or to a hot sponge, may be conscious of a feeling of stiffness in moving the bac according to the seat of the mischief. Sometimes—as in a in the cervical vertebræ placed on record by Mr Cæsar Haw a great increase of pain in the neck when the face is turne pillow to one side or the other, so that the hands are used head in every change of posture.

Intrinsic or myelitic symptoms.—After the "extrinsic" s lasted for weeks, months, or even for years—having been perh neuralgic or rheumatic—they are succeeded by others of wh origin is obvious. These "intrinsic" symptoms are by no results of mechanical pressure upon the cord. Very gr pressure by itself may probably alter the shape of the cord, only begin when the pressure interferes with its circulation a

As far back as 1856 Gull discovered in a case of this masses in the tissues of the cord; and more recently th spinal cord in compression-paraplegia has been thoroughl by Michaud and other French observers. The affected pa reduced in size (so that sometimes it is scarcely as thick flattened or distorted in shape. Its tissue may be pale, natural to the naked eye; or it may obviously have lost it ture. It is either softened or (in a more advanced stage) ha Under the microscope the neuroglia is seen to be thicker and

the nerve-tubes have no longer any medullary sheaths, but their axis-cylinders persist, and may even be increased in size. Granule-masses are abundant. The ganglion-cells are swollen, vacuolated, and pigmented, or sometimes they are degenerated and broken down. In other words, there is a chronic transverse myelitis, which extends a little way above and below the spot actually compressed; so that many cases of paraplegia due to disease of the vertebræ or other causes of compression of the cord are really cases of secondary myelitis.

The course of the paraplegia is such as might be inferred from the nature of the lesion causing it. Sometimes its development takes place very rapidly—within two or three days, or even in a few hours—much more often it occupies several weeks, or months. The patient finds his legs more and more heavy, especially in going up and down stairs; he becomes unable to stand; at last he cannot even move his toes while lying in bed. Subjective sensations of numbness, pins-and-needles, &c., often precede the motor symptoms; but, later on, loss of voluntary power over the muscles generally preponderates over loss of sensation. The upper limit of the spinal lesion is commonly well marked, especially if there is much anæsthesia. It corresponds more or less exactly with the seat of the early "extrinsic" pains and tenderness, which, indeed, often persist after paralysis has set in. A point of great importance is that there is little tendency for secondary changes in the cord to spread upwards in the main tracts beyond the point of compression. Sometimes the local myelitis from compression gives rise to ascending sclerosis of the posterior median columns without special symptoms; more frequently to *descending* sclerosis of the lateral columns.*

Reflex contractions in the lower limbs are usually much more readily excited than under normal conditions.†

The state of the bladder is very variable; it often continues to act naturally for some time after the legs have begun to be paralysed, but whenever the paraplegia is complete there is retention of urine.

Charcot lays stress on some forms of *paræsthesia* which, he says, although not peculiar to compression-paraplegia, are observed more frequently in these cases than in other affections of the cord. One is a retardation in the transmission of sensory impressions when there is not absolute anæsthesia; fifteen, twenty, or even thirty seconds may elapse between the application of a stimulus to the cutaneous surface and the perception of it by the patient. This symptom we shall meet with again as a symptom of Tabes dorsalis. Another is a peculiar dysæsthesia, a very painful feeling, which is excited by slightly pinching a limb or touching it with anything cold; this lasts for several minutes, and apparently no more exact description of it can be given than that it is a sort of diffused vibration. Another is an "associated sensation" which is referred to a spot upon the opposite limb corresponding exactly with that to which the stimulus is applied.

Diagnosis.—The determination of compression as the cause of paraplegia may be either very easy or very difficult. The simplest cases of all are those in which there is obvious spinal deformity, for the short round bend or sharp angle produced by Pott's disease is unlike anything else. But often the natural configuration is preserved.

* Erb quotes Michaud as having observed that in some very rare cases a morbid action may *ascend* along the lateral columns, so that the upper limbs may after a time become paralysed, although the part of the cord which is compressed is in the thoracic region.

† See on this point a recent paper by Dr Bastian, with remarks by Dr H. Jackson, Mr Bowlby, and Dr Buzzard ('Med.-Chir. Proc.,' February 25th, 1890).

Leyden says that if caries occurs in either the lumbar or region there is rarely any projection of the spinous processe being that the natural curve of those parts of the column is in direction; but if in these cases the patient is made to stoop head forward, it is not uncommon for some one of the cervic spines to appear unduly prominent. It is also important to obs the vertebral column retains its flexibility.

In malignant disease, if there is anything to be detected on r it is the presence of a new growth and not a mere displac bones. Cruveilhier, in his hydatid case (p. 473), discovered twelfth dorsal and first lumbar vertebræ a spot the size of a six felt like a depression surrounded by a bony ring, and which the remains of a spina bifida. As he says with regret, if he interpreted what he observed, and had ventured upon making the patient might perhaps have been cured.

Tumours and gummata are of course beyond the reach of r A careful analysis of the symptoms affords the only chance of d these cases from those of disease of the vertebræ unattended wit The peculiar severity of the pain caused by malignant growth a diagnosis to be made between that particular form of comp plegia and the rest.

It is often difficult to distinguish cases of caries of the ve meningeal tumour from those of primary *transverse myelitis*, or affection of the interior of the cord limited to a particular segme is often accompanied by painful sensations referred to various body, and by the peculiar "girdle-feeling"—phenomena whic comparable with the "extrinsic" symptoms of compression-pa which do not always differ from them even in degree. We that in some cases diagnosis between the two forms of dis between primary and secondary myelitis) is impossible.

It is chiefly at an early period that a case of compressi might be mistaken for one of *rachialgia*. The suggestion has, made that, considering the frequency with which this spina associated with hysteria, one ought to be prepared for its be then accompanied by hysterical paraplegia, so as very closely grave disease of the vertebræ. It is probable that in such a c careful examination of the patient would show a want of co between the apparent upper limit of the lesion in the cord, ar tenderness and pain in the spinal column; but as a fact we do cases of rachialgia are complicated by hysterical paraplegia.

Prognosis.—Most forms of paraplegia by compression end in the patients, but their duration is very variable.

According to Leyden, *cancer* of the vertebræ commonly of some months, sometimes of more than a year; it kills, cachexia and wasting with dropsy, or more directly by interfe cord. Among fifteen recent cases in Guy's Hospital (1888) from the earliest symptoms till death, was three months in year in eight, and fifteen months in one patient. When the vertebræ are affected, the fatal issue is sometimes preceded by stupor, for which no explanation can be found in the autopsy.

Meningeal *tumours* are described by Erb as slower in their cases end in eight or ten months, others in from two to five

last longer still, even to a period of fifteen years. In one of the two recent cases above given (p. 474) the duration of the disease was sixteen months, and in the other two years, if we reckon from the time when pain in the back was first complained of; and both patients may be said to have died accidentally—the one of pneumonia, the other of renal suppuration.

The only variety of paraplegia from compression in which recovery of power over the limbs appears to be possible, is that due to *caries* of the spine. Of such cases a great many do well; among six which came under Erb's observation during the year before he wrote his article on this subject, only one ended fatally, the remaining five being cured or greatly relieved. Charcot refers to two patients, who had their lower limbs completely paralysed for eighteen months and two years respectively, and who nevertheless recovered perfectly.

One might well have doubted whether in these cases of caries of the vertebræ, in which recovery takes place from secondary compression-paraplegia, inflammation of the substance of the cord has ever occurred, But an observation of Michaud, which is cited by Charcot, shows that this really is so. A woman who had regained the use of her legs for more than two years, died of hip-joint disease. The cord, at the level of the spinal affection, was found reduced to the thickness of a goose-quill, its sectional area being not more than one third of that of a healthy cord in the same region. It was of firm consistence and grey in colour; in other words, it seemed to be affected with sclerosis in an advanced stage. The microscope, however, showed that a considerable number of nerve-fibres possessing medullary sheaths were embedded in the thick dense fibrous material which gave it these appearances. Only one of the grey cornua remained, and this displayed but a small number of uninjured nerve-cells. This case has been already cited in proof of the possibility of recovery from myelitis (p. 445).

Treatment.—The most important means of treatment in cases of paraplegia from angular curvature is complete rest in the recumbent and, as much as possible, in the prone position.

When from any cause this is impracticable, or when it has been continued with good results, and the patient is first allowed to sit up, a valuable means of securing rest for the diseased part is Sayre's method of applying a plaster-of-Paris bandage, rolled round the body while the patient is suspended from the head, chin, and armpits by a suitable apparatus.

Cod-liver oil should be administered, and every effort made by fresh air and good food, particularly of a fatty nature, to combat the tubercular process.

At the present time (March, 1890) the writer has under his care a case of complete motor and sensory paraplegia from vertebral caries in a young woman of twenty-three. She has been the subject of angular dorsal curvature since childhood, with tubercular disease of one hip-joint: and for seven months had been completely paralysed up to the waist, with some vesical symptoms in addition. Following the practice of some American surgeons, large doses of iodides of potassium and sodium were prescribed (half a drachm every two hours), and though much distress from iodism was produced, the treatment was persevered with, and now after several weeks she is taking ten grains of the potash-salt every four hours. The result is that sensation has been completely regained, and that she is able to move her legs freely in bed.

Charcot speaks in decided terms of the value of the app actual cautery along both sides of the projecting spinous pr has been used in two ways, by searing the skin on each side or by making deep incisions and cauterising the wounds. of each the present writer would dissuade from the latter me

Of late years antiseptic surgery has ventured to deal w from compression by the products of vertical caries. Seve been recorded in which the laminæ have been exposed, resected, and the carious material cleared out: and this se has occasionally been successful. Mr Lane recently perform tion on a lad in Guy's Hospital, with the gratifying result o power of walking ('Brit. Med. Journ.,' April 20th, 1889).

It is probable that mercury and iodide of potassium curing paraplegia which is due to syphilitic gummata p growing into, the cord; and this treatment should never any case which may possibly be of venereal origin.

Mr Horsley has published a remarkable case in which h spine in a patient of Dr Gowers, who had diagnosed the intra-vertebral tumour pressing on the cord. The tumour removed, and the patient was not only relieved from excruci but was restored to power of locomotion. So brilliant a combination of the skill of the physician in detecting and t surgeon in removing an organic lesion can scarcely be mo event; but even one such case encourages the most minute ef and define organic diseases, and amply justifies the bol measures when so directed ('Med.-Chir. Trans.,' 1888).

Spastic Paraplegia.*—Rigidity of the paralysed limbs i feature in the later stage of segmental disease of the cord, w or due to compression. It is only when the lowest lumb destroyed that the legs are of necessity flaccid. In parapleg curvature and in hysterical paraplegia they are often spasmo more frequently, both in cases due to caries and in those of pr they are forcibly extended. We shall find that similar cont of a "tonic" kind, is a late result of lesions of the brain; and the paralysed limbs become rigid soon after the paralytic str

In the cases we are now concerned with, the toni ("contractures") and rigidity are late, not early. They c after paraplegia, and they are associated with increased refle superficial and deep, and with the clonic contractions known They are no doubt due to increased reflex irritability of the and this again may be referred to the absence of the normal fluences from the centres above the seat of lesion. The diffi plain why their appearance is delayed; but it seems to be alw with descending sclerosis affecting the deeper part of the mo lateral columns, either from a focus in the encephalon, as a cl from one in the cord, as a segmental lesion from compression

The contraction of the limbs is in most cases obviously their paralysis, for it generally does not show itself until already lost power over his legs for a considerable time.

* *Synonyms.*—Spastic spinal paralysis (Erb)—Tabes dorsalis spa (Charcot)—Primary and secondary lateral sclerosis—Spasmodic paralysis

secondary rigidity and spasm of muscles which have already lost voluntary power are probably of the same pathology, whether paraplegic, hemiplegic, or monoplegic in distribution.

There are, however, other far less common cases in which rigidity is present from the first, and, indeed, constitutes the most marked symptom, so that it may seem to be the only obstacle to the patient standing or walking. Here also the lesion is in all probability a symmetrical *primary* sclerosis of the lateral columns—the crossed pyramidal tract and especially its hinder parts—leaving the anterior grey cornua intact. Satisfactory evidence on this point was afforded by a case of Dr Morgan's, of Manchester, in which Dr Dreschfeld found sclerosis of the crossed pyramidal tracts and no other lesion, spinal or cerebral ('Transactions of the International Medical Congress of 1881;' and also 'British Medical Journal,' vol. i, p. 407). Spastic paraplegia, whether secondary or primary, is therefore anatomically a "systemic" or "columnar" disease (p. 488), the sclerotic process keeping to a definite tract of fibres.

Spasmodic paraplegia is said to occur chiefly in persons between thirty and fifty years of age, and in men more often than in women. Of Dr Morgan's seven cases only one occurred in a woman. Erb speaks of it as very frequent. In this country primary spastic paraplegia is certainly rare, while the secondary form of the affection is common. Its causes in the former case are unknown. Poisoning by syphilis and by lead have been suspected, and also by *Lathyrus cicera* in three cases reported from Italy.

Symptoms.—The lower limbs assume as a rule a position of rigid extension and adduction. The contraction may vary indefinitely in degree. At first it is only occasionally present, and is generally less marked when the patient is lying down than when he stands upright. One of the earliest symptoms of the complaint is a peculiar gait. In walking the foot is lifted with difficulty; the toes are scraped along the floor and catch against every inequality in the surface; the step is short and hesitating, and sometimes there is a peculiar hopping movement, the body being raised upon the toes at each step. Very often the attempt to walk causes a tremor in the foot and leg, which may extend to the trunk also,—a true clonus. In some cases the back is arched, and the head thrown backwards; in others the body is bent forwards over the toes by similar tonic contraction of the flexor muscles of the trunk, so that there is danger of falling, especially in descending stairs. The gait at one stage may be rolling or waddling, as carefully described by Dr Ross. The legs feel weak and heavy and are easily tired. Sometimes, if the patient sits down, his legs are thrust forward, so that his feet do not touch the ground. In more extreme cases he is confined to bed, and is perfectly helpless. His knees are tightly pressed together by spasm of the adductors, and cannot be bent from spasm of the quadriceps. Yet in primary uncomplicated cases there is no impairment of sensibility, pain is entirely absent, and the bladder and rectum perform their functions naturally. The galvanic and faradic contractility of the muscles is slightly lowered, but there is no reaction of degeneration. In cases secondary to myelitis or compression these negative characters are often wanting.

There is exalted susceptibility to "tendon-reflexes." Not only are the common movements induced by percussion of the ligamentum patellæ exaggerated, but movements can be excited through the tendons of the tibialis anticus and posticus, the biceps femoris, and even through aponeurotic structures. Ankle-clonus is present. There is sometimes, but not always,

increase of the superficial reflex movements which are excite impressions.

The *course* of spastic paraplegia is progressive, but very s a period of eight, ten, or fifteen years; sometimes it remain the same point for a long time. It may never extend abo it may at length affect the lumbar and abdominal muscles limbs. The abdomen then feels hard, and is separated from of the chest by a furrow. The fingers are, from time to nently, clenched within the palm; there is extension of the w joints, with pronation of the forearm; the arms may be fixed side of the trunk. One leg is often affected before the contraction may then spread to the arm of the same side volves the opposite leg. Occasionally the upper limbs are attacked. Erb says that it rarely happens—and only at th of the disease—that the lower limbs are rigidly flexed, in extended.

Dr Savage has observed cases of spastic paraplegia going lopment of general paralysis of the insane. We have had case of this sequence in a man under treatment in Philip the greater part of the year 1889.

According to Charcot and Erb the only real difficulty in d disseminated sclerosis in that form in which the symptoms the higher centres happen to be wanting. Charcot adds tha cases with which he used to illustrate his lecture on "sps scattered patches of sclerosis were found at the autopsy as h cerebri.

Spasmodic paralysis in children.—Dr Gee recorded in the sixteenth volumes of the 'St Bartholomew's Hospital Repo cases which he called "spastic paraplegia." They all occur and the complaint was either congenital or began in early i were eight cases, six girls and two boys. The legs were and sometimes the arms. The contractions corresponded in closely with Erb's and Charcot's descriptions. Dr Gee lay fact that handling the limbs increased the rigidity. Chlo it in all cases but one; in that instance the muscles of one c wasted, the disease having lasted eleven years.*

Seeligmüller, Erb, and Gowers have also described spa in children. In some of these cases it was of the variet Charcot as "sclérose latérale amyotrophique," in which affected muscles is present, and the anterior cornua as well columns are affected. In other cases the symptoms were cerebral rather than a spinal lesion.

During the last few years we have had two cases in Guy in a boy of three, the other in a girl of seven, both probably

Mixed forms.—Lateral sclerosis of the cord may be con may complicate, other diseases. It is, as we shall see, a fre the normal, sequel of cerebral hæmorrhage; and, as already more often seen as a sequel to transverse myelitis or segmen of the cord than as a primary affection. But beside these co

* See also Dr Gee's paper on "Hereditary Infantile Spastic Paraplegi in the twenty-fifth volume of the same 'Reports' (Jan., 1890), in which paraplegia with some muscular atrophy of the arms in a father and two

secondary spastic paraplegia, it is not unfrequently also found combined with other columnar diseases.

Thus, it not unfrequently supervenes in the later stages of insular sclerosis (v. *infra*, p. 540); it is sometimes followed by extension of the sclerotic process from the lateral columns to the anterior cornua, or perhaps more often primary atrophy of the anterior cornua is complicated by secondary descending lateral sclerosis. The result is a combination of progressive muscular atrophy with spastic paralysis (*infra*, p. 502).

Prognosis and treatment.—Erb has seen two cases of spastic paraplegia almost cured and several much relieved by galvanic currents applied to the spine. He also speaks favourably of the "cold-water cure," and of the gaseous saline baths (*Sool-baden*) of Rehme and Nauheim. He has found the nitrate of silver sometimes useful as an internal medicine, and Charcot recommends the bromides. Strychnia is likely to do harm rather than good. Conium and belladonna have been given without any good results. In some cases to be presently mentioned, physostigma has been of great service. According to Dr Ross, the galvanic current is by far the most trustworthy remedy, but Dr Gowers believes that faradism is harmful, and that galvanism has no influence in lessening the spasm or improving the strength. As he well puts it, in primary lateral sclerosis the chance of recovery and the danger to life are both small.

Clinical cases of spasmodic paraplegia.—In patients suffering from chronic paraplegia the spasmodic symptoms above described are very frequent in any large hospital; but we have had very few cases at Guy's Hospital which answer to the accounts given of primary spastic paraplegia.

In eight or nine instances contraction of the lower limbs has been apparently the primary disease; but the legs and thighs have been drawn up in a state of flexure instead of being stretched out. Any attempt to straighten the limbs has generally caused great suffering; but in one case—that of a man aged thirty-three, under Dr Wilks's care—the suspension of a weight of fourteen pounds to the right foot led to a marked diminution of the pain; the limb was bent, so that the heel almost touched the buttock, and it could not be put straight even when chloroform had been inhaled. In certain instances the extract of *Calabar bean* appeared to remove the rigidity altogether.*

These cases belong to a different clinical type from those described by Charcot, and have possibly a different pathology. Contraction of the

* The following are the cases referred to:—1. The first case in which I observed this satisfactory result was that of a boy, aged six, who was admitted on August 19th, 1874. He had been well until three weeks previously. He lay on his right side, with his legs drawn up, and unable to move them. They could be forcibly extended, but then became rigid. The expression of his face was indicative of pain, and he had complained of pain in the back of the head and over the spine. Sensation was unimpaired, but the fæces and urine were often passed into the bed. He could close his hands, but with a very feeble grasp, and sometimes they were noticed to be stiff. The diagnosis was chronic spinal meningitis, and hydrarg. c. creta, iodide of potassium, bromide of potassium, and other medicines were given without any result up to the 8th of October. At that time he began to take the extract of physostigma in doses of one sixth of a grain, gradually increased to half a grain, three times daily. Improvement quickly set in; the limbs became less rigid, and he regained the power of moving them. On November 21st cod-liver oil and steel wine were substituted for the Calabar bean. On January 9th, 1875, he left the hospital, able to walk pretty well without help.

2. In 1876 I was asked to see a boy, aged fourteen, who was under Mr Cooper Forster's care, with contraction of the thighs and legs, which had been coming on for six months. He appeared to suffer intensely from pains in the affected limbs, and screamed when they were touched. The legs and thighs were much wasted. Remembering the former case, I

legs in a *flexed* condition, apart from primary disease of the joints, may supervene in the last stage of chronic diffused myelitis, of compression-paraplegia, of infantile atrophic paralysis, and even of primary lateral sclerosis itself. It may also occur in hysterical paraplegia; but the "cadaveric" position with extended hips, knees, and ankles and adducted feet is characteristic of the clinical type of Charcot and Erb.

A well-marked case of the more common secondary form was during four years under the writer's care in Guy's Hospital, and ended in recovery. The patient, a boy of twelve, when first admitted in January, 1885, suffered from caries of the cervical and of the lower dorsal vertebræ, which afterwards produced both lumbar and psoas abscesses. There was no anæsthesia or serious disturbance of the bladder or rectum, or bedsores, or pain. The muscles were not atrophied except from want of use. When first admitted there was tonic contraction of both arms and both legs, the former flexed, with *main en griffe*, the latter extended in the cadaveric position. Knee-jerks and plantar reflexes were exaggerated, and ankle-clonus was readily elicited. Faradic contractility was unaffected. Physostigma was pushed without benefit; but after many months, as the result apparently of improvement of the vertebral disease by surgical treatment, the power of his arms gradually became almost normal, and contraction disappeared; he could move his legs well, although clonus and exaggerated reflexes remained,

prescribed the Calabar bean in doses at first moderate, but quickly increased. The symptoms at once began to subside. He was after a time transferred to my charge, and left the hospital cured.

3. On October 31st, 1876, a woman, aged forty-one, was admitted under my care with a spinal affection which had come on suddenly two months before. She first complained of pains in the leg-muscles and then of stiffness in the joints. This was followed by great weakness and wasting of the lower limbs; and then they slowly began to contract. She lay in bed with her legs strongly flexed; when they were forcibly straightened it gave her great pain. Faradic contractility was found to be much diminished, and she had partial loss of sensation; she could not pass her water. She took at first half a grain of extract of physostigma three times daily; after a week this dose was doubled, and four days later it was trebled. By this time she could move her legs to some extent. The medicine was continued for a month, and then some tincture of iron was prescribed. By December 23rd she could straighten her legs perfectly well. In the month of February, 1877, she became able to stand and to walk without help, and on March 1st she was discharged cured.

4. In 1878 a sailor, aged twenty-eight, came into the Clinical Ward under my care on May 29th. Fourteen months previously he had been on a river in South America loading timber, and had repeatedly got wet through and allowed his clothes to dry on him; he said he was well used to getting wet with salt water but not with fresh water. Four or five days after he left off this work, he one morning on waking found that his left leg was stiff and painful in the ham. As the rigidity gradually got worse he went into hospital at New Orleans, and after a time it passed off. He returned to work, but two months later, the weather having been bad, he again began to suffer from stiffness and pain in the left leg. Presently the right one also was attacked. They both became weak, and for six weeks before admission he could not walk without a stick. At times he had short attacks of convulsive twitchings in the left leg. I found the muscles of the thigh decidedly rigid on both sides, especially the left. After leaving him for a few days without treatment, I prescribed the extract of Calabar bean in doses of a quarter of a grain, afterwards increased to one grain. Improvement was not at first very striking, but at the end of thirty-four days there was hardly any rigidity left.

5. The only case that I know of in which the extract of physostigma produced any unpleasant effects is one recorded in vol. xviii of the 'Guy's Hosp. Rep.' A boy, aged ten, had been suffering for some months with paraplegia before rigidity of the legs set in. A quarter of a grain of the extract was ordered, and after a week it was increased to half a grain three times daily. By mistake he took a grain in one dose, and an hour afterwards he was blue in the face but perfectly conscious, perspiring profusely, a clear froth coming from the mouth, the pupils of natural size, the hands cold, numb, and almost powerless. He had an emetic, and in three hours he was as well as before.—C. H. F.

and his general condition greatly improved. Finally he was discharged in 1889, able to walk and use all his limbs, free from spasm, and only showing the angular curvature of his spine, and the scars of healed abscesses.

Of *primary* spastic paraplegia the writer has only seen two cases. Both patients happened to be clergymen. The one, a remarkably healthy, well-developed man of about forty, complained of gradually increasing difficulty in walking owing to "stiffness" of the legs. He could not bend his knees, and found it almost impossible to ascend a broad and shallow flight of stairs. When lying down his legs were rigidly extended. Ankle-clonus was present and the knee-jerks were increased. There was no pain except during occasional cramps or spasms in the legs. The pelvic organs were unaffected. There was no true paraplegia, for the lower limbs could be moved readily until the check of stiffness came, and the skin was normally sensitive. The muscles were of good size. Physostigma was prescribed, and he thought there was some improvement after several months, but if any it was slight. He afterwards tried massage and other plans of treatment, but the local disease went slowly on until his death by an acute attack of inflammation of the lungs.

The other case occurred in an older man—one who had been an Alpine climber and enjoyed robust health. In his case also the loss of locomotive power only resulted from stiffness of the legs. The knees were bent, the body was bowed, as if with the "chronic rheumatism" of an aged peasant, so that it was almost impossible for him to walk or to stand upright. The pelvic organs were unaffected; knee-jerks were readily produced and clonus also. As in the previous patient, the upper limbs were free. In this case also physostigma was fully tried with only doubtful benefit, but under repeated courses of nitrate of silver decided improvement took place, whether in consequence or not must be doubtful. At present he enjoys good health, but the spastic paraplegia remains.

Affections of the Spinal Membranes.—This is a convenient place for a brief mention of certain lesions of the meninges of the cord which do not produce by the local action any constant sequence of symptoms so as to enable us to class them with other causes of "compression-paraplegia" or of atrophic paralysis. They are not segmental, but indiscriminate or diffuse, in their localisation.

Spinal meningeal hæmorrhage.—Except as the result of severe injuries, which come under the care of the surgeon, this is a very rare lesion. The causes assigned to it by authors are violent bodily efforts, convulsions, purpura, and the suppression of a hæmorrhoidal or a menstrual flux. If a diagnosis is to be made during life, it must be based upon the sudden development of the symptoms, and upon the co-existence of symptoms of irritation of the cord and its nerves with those of compression of these structures. Certain cases, in which there have been severe pains in the back and limbs, rigidity of the spine, and partial paraplegia, have been attributed to the effusion of blood into the spinal membranes; and this explanation has not been regarded as invalidated when recovery has slowly taken place. But it would seem that in other cases in which meningeal hæmorrhage has proved fatal, so that it has been demonstrated in the deadhouse, the symptoms have not been equally characteristic.

Tumours of the spinal meninges have been already described in their clinical place as causes of paraplegia by compression of the cord (p. 474).

Acute spinal meningitis.—Inflammation of the vertebral dura mater or spinal pachymeningitis is a frequent result of caries of the vertebræ, and forms part of the anatomy of paraplegia from compression.

Secondary inflammation of the spinal membranes may result from the invasion of a deep bedsore over the sacrum. In some cases the vertebral canal is actually opened by sloughing of the fibrous membrane which closes its lower end; in others, perhaps, the morbid process extends inwards along the posterior sacral foramina. At least four instances of this kind have been observed at Guy's Hospital, and probably several have been overlooked. Pus has generally been diffused among the nerves of the cauda equina, and beneath the spinal arachnoid, up to the base of the brain. In one case the inflammatory products lay outside the theca vertebralis. No distinctive symptoms seem to have been noted in the cases in question.

Other forms of acute spinal meningitis accompany myelitis and traumatic, tubercular, epidemic, and other forms of cerebral meningitis, which will be fully described hereafter. Hæmorrhagic spinal pachymeningitis is also occasionally found in association with a similar affection of the cerebral dura mater. Primary acute inflammation of the spinal membranes does not appear to exist.

Chronic spinal meningitis.—Certain local forms of meningitis, occurring chiefly in association with syphilitic gummata, or with caries of the vertebræ, have been already mentioned; but it sometimes happens that the whole of the spinal membranes are found matted together and thickened round a cord which appears to be perfectly healthy. In 1878 a case of this kind was found in an old woman of seventy, who had for about a year been suffering from slowly advancing paraplegia. She had no spasms or rigidity of the legs; she lay helpless in her bed, but the lower limbs still retained some power of sensation, so that she could distinguish heat from cold. She complained of pains in the legs, apparently not severe, and in the lower part of the abdomen. After death the visceral arachnoid, when it had been stripped off the inner surface of the dura mater, was found to be as thick as a sheet of writing-paper. In the lower part of the dorsal region the adhesion of the membranes to the cord was unusually close for about an inch and a half of its length. The thickening extended upwards around the pons, and to the under surface of the cerebellum, so that the cerebro-spinal aperture was closed. Dr Frederick Taylor (under whose care the patient was during life, could detect no morbid change in the cord itself except that the fibrous septa entering it from the surface appeared thicker than usual.

A similar case was recorded by Gull in his well-known paper in the 'Guy's Hospital Reports' for 1856 (Case 7). In that instance rigid flexion of the legs was a marked symptom, and they were also affected with frequent spasms. But may not this have been a case of transverse myelitis in the upper dorsal region, with exalted excitability of the cord below from secondary descending lateral sclerosis?

Charcot first described a form of primary inflammation of the spinal dura mater, producing pain and partial paralysis, in one or the other arm—*Pachymeningitis cervicalis hypertrophica.* The origin of the ulnar nerve seems most often to suffer; and, after paralysis with pain and atrophy of the arms, there follows secondary spastic paraplegia of the legs. We shall meet this affection again in the next chapter (p. 503).

Some modern German writers describe chronic diffused spinal meningitis as of frequent occurrence, and as being often recognised during life without

much difficulty. It is characterised, says Erb, at first by pain and stiffness in the back, a troublesome "girdle sensation," a feeling of weight in the legs, numbness, tingling, tearing, or dragging pains in them, and cutaneous hyperæsthesia. After a time partial paraplegia develops itself, which varies in degree from day to day. Erb supposes that such fluctuations depend upon alterations in the quantity of fluid effusion within the spinal canal, or perhaps in the amount of blood in the vessels about the cord. There is generally but little impairment of sensibility; and, according to Braun, the sphincters retain their functions. Erb speaks of the morbid change in the membranes as being usually but little marked; they are more or less thickened, opaque, and adherent to one another; and there is an excess of fluid round the cord. Cold is said to be the chief exciting cause of this affection; it has often been observed in soldiers after severe fatigue and exposure during a campaign. It commonly begins acutely, and afterwards passes into a chronic form. In many cases it becomes complicated with myelitis, and the peripheral part of the cord beneath the pia mater sometimes undergoes sclerosis in an annular form.

How far one is justified in maintaining an anatomical diagnosis in cases of this kind is doubtful. But the clinical differentiation of them appears to be important, as regards prognosis and treatment.

Erb says that many prove fatal by bedsores, cystitis, or exhaustion; but he admits that others recover more or less completely; and Braun declares that the prognosis is favourable if the acute stage, in spite of the increasing paralysis, be treated at first with local bleeding and cold applications. Afterwards, when paralytic symptoms alone remain, the patient should begin a steady course of hot brine baths, those of Rehme or Nauheim being preferred, which closely resemble the saline waters of Droitwich. Erb endorses Braun's statements, and declares that when there is no myelitis, baths at high temperatures (98°—108° Fahr.) are well borne, and that the reputation of curing spinal paralysis in general which is possessed by hot springs is really derived from their success in this particular class of cases. Hitzig and Erb have found benefit from passing galvanic currents along the spine. Iodide of potassium is given; but good food, wine, and tonics are recommended as important auxiliaries in the treatment.

PARALYSIS ATTENDED WITH MUSCULAR WASTING

THE affections discussed in the last chapter are all, we found, accompanied by paraplegia; and when their anatomical seat is ascertained, it is a lesion of the cord which is "indiscriminate," *i. e.* whether it affects the whole organ, as diffuse myelitis, or one or more segments only, as transverse myelitis and paraplegia from compression, or the surface, as meningo-myelitis, or the deepest parts, as peri-ependymal myelitis—in all these varieties of disease, the cord is affected indiscriminately throughout the diseased segments.

The only exception was spastic paraplegia, where the lesion is in the most typical cases limited to the crossed pyramidal tracts of the cord.

There are several other spinal diseases which agree with spastic paraplegia in this particular: they affect particular tracts of the cord, and as a rule do not transgress these anatomical limits. Moreover, they are chronic in their course; they are much less dangerous than acute myelitis or paraplegia from compression; and the anatomical process which presumably causes their symptoms is the same—chronic interstitial myelitis, *i. e.* grey degeneration or sclerosis. They are called by German pathologists "system-diseases," an uncouth and obscure phrase in English. "*Longitudinal*, as opposed to *transverse*, chronic myelitis" would express their range. Perhaps the term "columnar" sclerosis may serve to denote the characteristic limitation of the lesion to the longitudinal columns or tracts of the cord.*

* The recognition of the physiological division of the white substance of the cord into distinct tracts of ascending and descending fibres is due to Türck, of Vienna, who in 1851 and 1853 described them as regions of secondary degeneration after lesions of the brain and cord. Flechsig subsequently showed that the same distinction is observable in development, the fibres of the anterior column and anterior root-zone acquiring their myelin first, those of Goll's tract and the direct cerebellar tract next, and the crossed pyramidal tracts last, not indeed until some weeks after birth. (See Dr Bramwell's excellent plates, 19, 20, 21.)

The longitudinal, columnar, or systemic scleroses which have been as yet observed are the following:

1. Of the lateral columns (crossed pyramidal tract) rarely primary, often secondary; descending from a primary lesion of the motor tract in the brain or cord. The corresponding disease is that described in the last chapter as Spastic Paraplegia.

2. Of the antero-median column of Türck. This is always secondary and descending. It does not correspond to any known clinical group of symptoms.

3. Of the posterior columns of Burdach (*fasciculi cuneati*). This is usually primary, and corresponds with the clinical malady which will be described in the following chapter as Tabes Dorsalis.

4. Of the postero-median columns of Goll. This is almost always a secondary lesion, often combined with the last in tabes, sometimes appearing as an ascending degeneration from a transverse lesion. No constant symptoms are known to answer to it.

5. Of the direct cerebellar tract. This is always secondary and ascending. It also does not give rise to any ascertained malady. Secondary sclerosis of the "mixed tract" outside the anterior root-zone (antero-lateral column) has been observed by Dr Gowers and by Dr Tooth. It occurred as an ascending degeneration after fracture of the spine. Its pathological significance is as yet unknown ('St Barth. Hosp. Reports,' vol. xxi).

6. Of the large motor and trophic ganglion-cells of the anterior cornua. This is sometimes an acute, sometimes a chronic process, and is often confined to a single segment or to some part of the anterior cornu in a single segment. The cells which form the posterior vesicular column of Lockhart Clarke appear also to be subject to a destructive process which affects them alone.

In the present chapter we deal with affections for the most part identified with the last of these "systemic" scleroses. But they are also united by a common symptom, that of marked and rapid atrophy of the paralysed muscles, as well as negatively by the absence of anæsthesia, trophic changes in the skin, or affections of the bladder and other pelvic organs.

They may for the present be called in common Atrophic Spinal Paralyses.

ACUTE ATROPHIC PARALYSIS.*—In the last century this affection was described by Underwood in his treatise on the 'Diseases of Children' (1784). Jacob von Heine published a monograph on it in 1840, and this writer and afterwards Duchenne expressed the opinion that the cause of infantile paralysis was a lesion of the spinal cord. When autopsies failed to reveal any morbid change, MM. Rilliet and Barthez proposed the name of "paralysie essentielle;" but since 1863 more refined histological methods have shown that the anterior cornua of the cord are diseased. Accordingly the affection is now known as "poliomyelitis † anterior acuta." The old name "infantile paralysis" is not wide enough, for it is now ascertained that the same disease occasionally occurs in adults.

Onset and course.—A child who is about to suffer from acute atrophic

* *Syn.*—Acute amyotrophic spinal paralysis—Poliomyelitis anterior acutissima (Kussmaul)—Anterior cornual myelitis (Gowers)—Infantile paralysis—Wasting palsy of children.

† *I. e.* myelitis affecting the *grey* matter (πολιός). Charcot proposed Tephromyelitis, τεφρός (ash-coloured, cinereous); and Vulpian, Spodiomyelitis (σπόδιος, also ash-coloured, like the last, but an epithet only used in poetry).

paralysis is sometimes apparently well until the loss of power appears. But more often he falls ill with febrile disturbance, oppression, or drowsiness. Sometimes the earliest symptom is an epileptiform convulsion, or there may be spasmodic twitchings of the face or limbs, grinding of the teeth, and rolling of the eyes. The fever usually lasts a day or two, but it may pass off in a few hours, or may continue for a week or longer. Convulsions may be repeated during twenty-four or forty-eight hours.

When the child seems to be getting better, and is being washed or dressed—or perhaps when it first attempts to stand—the mother or nurse finds that one or more of the limbs is powerless. He has gone to sleep at night with full use of his arms and legs, and in the morning a limb may hang flaccid and motionless. The affection may be a monoplegia, the paralysed limb being most often the right leg, but sometimes an arm; or it may be a paraplegia, or a hemiplegia, or a crossed paralysis of one arm and the opposite leg. Sometimes there is loss of power of the trunk or of all four limbs, and sometimes they are attacked in succession at intervals of a few hours.

Occasionally the initial fever is very slight; it may perhaps be absent, and the paralysis be the first symptom that the child is unwell. But, as might be anticipated, there is no thermometric evidence of this.

It is characteristic of acute atrophic paralysis that the affected parts are completely relaxed. No reflex movements can be elicited, whether by stimulation of the skin or of the tendons. On testing the muscles with faradic currents, one finds that their contractility becomes markedly diminished within the first four or five days, and that it is entirely extinguished at the end of a week or a fortnight, but the susceptibility to galvanic currents is increased. In other words, the reaction of degeneration is present. Rapid and early wasting of the muscles takes place. Formerly they were said to undergo fatty degeneration, but the histological changes are really of a different kind, and correspond exactly with those described at p. 401 as following lesions of the nerve-trunks. The surface of the paralysed limbs is cold, and they are pale or of a livid bluish tint; the volume of the pulse in them is said by Volkmann to be diminished, and Charcot states that after death the main blood-vessels are found remarkably reduced in size.

As a rule, no impairment of sensation can be detected: the child cries lustily as soon as the poles of a galvanic battery are applied. The functions of the bladder and rectum are unaffected, and bed-sores do not appear.

Unlike most forms of paralysis, that now under consideration shows no tendency to gradual increase. The limbs are often attacked one after another, but the loss of power in each of them, although not absolutely sudden, becomes complete within a few hours. Erb says that the whole development of the disease, in successive outbreaks, may be protracted over a week, but it generally occupies much less time.

No long period elapses before recovery begins to take place; sometimes this is observed within a few days, more often in the course of two or three weeks. Even muscles which have to some extent undergone wasting regain their size and strength. If the arms and the upper part of the trunk are affected they are particularly likely to get quickly well. In the course of a few months the disease may entirely disappear, especially when it is confined to a single limb. Some writers have disputed the claim of such a "temporary paralysis" to be classed with those forms in which there is perma-

nent loss of power; but most likely it is the same disease. These favourable cases are, however, very exceptional. Usually the recovery is incomplete. It goes on for a month or eight weeks, so that the parents of the child cherish the most pleasing hopes; but after this the progress becomes slower, and at the end of six or nine months it ceases for ever.

The condition of the little patient at this time is very variable. One limb or two may be powerless and shrunken throughout, or the affection may have become limited to certain parts of an arm or of a leg. As a rule, the distal parts are more apt to suffer than those nearer the trunk. Volkmann, however, speaks of one patient as having a muscular forearm attached to a humerus like a stick, and Erb says that the deltoid sometimes suffers alone. Nay, the acromial part may escape, while the rest wastes away. Certain muscles exhibit a peculiar independence, some by remaining paralysed when those near them get well, some by recovering while the others are undergoing atrophy. The following usually escape: the *supinator longus* of the forearm, the *tensor fasciæ latæ* and *sartorius* of the thigh; while the *deltoid*, *serratus magnus*, *quadriceps extensor*, *gastrocnemius*, and *peronæi* are apt to suffer; or the last-mentioned may suffer alone, and the extensors in front of the leg escape.* When a muscle wastes, the destruction of its fibres is not necessarily made manifest by a corresponding diminution of its mass, for interstitial development of adipose tissue often takes place, which may entirely conceal it. Erb says that this is particularly apt to occur in young children, and that a muscle may actually appear bigger than in the opposite healthy limb, although it scarcely contains any contractile fibres.

Another peculiarity of parts affected with this disease is that they do not grow at the natural rate. Hence a paralysed limb is commonly shortened to the extent of an inch or an inch and a half, and sometimes by as much as eight inches. Even the corresponding half of the pelvis may remain undeveloped. The bones are thinner and more spongy and their processes smaller than on the healthy side. Remembering Hilton's observations with regard to the arrest of growth in the feet of patients suffering from disuse of the hip or knee-joint, one might be disposed to refer all these conditions to disuse, but this is certainly not the case. The disused muscles of hemiplegia are small and flaccid, but they do not atrophy like these. Moreover, the muscles waste even when the paralysis is partial, so that the child halts very little and is on its legs all day. Volkmann saw persistent failure of development follow four or five cases of "temporary paralysis," in which all the muscles recovered.

But the most important remote effects of acute atrophic paralysis in children are the contractions and deformities which are so commonly observed. Twenty years ago, Dr Wilks insisted on the fact that club-foot, when not congenital, is the result of paralysis, and not primarily a spasmodic affection; and this view, which was opposed by "orthopædic" surgeons, is now generally accepted by pathologists. Until recently, the accepted explanation was that contraction was generally the result of the unopposed action of the antagonists of the muscles paralysed. But Hüter and Volkmann have shown that when there is loss of power in several

* On this curious distribution of paralysis, seen also in the chronic form of atrophic paralysis and in lead palsy, light is thrown by the interesting experimental evidence, obtained by Professors Ferrier and Yeo, on the motor roots of the nerves of the extremities in the ape ('Proc. Royal Soc.,' March, 1881).

groups of muscles, it not infrequently happens that those on which the paralysis is most marked lie *within* the open angle formed by the displacement of the bones at a joint. For example, a *genu recurvatum* with the concavity directed forwards may appear when the extensor muscle of the knee is powerless, or a *talipes equino-varus* when no contractions can be obtained by galvanising the calf of the leg. Volkmann explains these facts by showing that they are in part due to the influence of gravitation; thus the weight of the foot causes the toe to point downwards when the limb hangs in the air. But another important factor is the gradual strain on a joint, in efforts made by the patient to employ the weight of the body as a propelling force. Volkmann points out that when a person whose thigh-muscles are paralysed learns to walk without crutches, he swings the trunk forwards so as to extend the knee as fully as possible. The result is that after a time the ligaments behind the joint yield, and the knee becomes bent the wrong way. The articulations in such paralysed limbs often become exceedingly loose. Lastly, a subordinate element in the causation of deformities is the contraction of the new connective tissue developed in the interstices of the wasted muscles, a result which has been compared to "sclerosis" of the cord and "cirrhosis" of the liver.

Distribution.—Putting together sixty-two cases collected by M. Duchenne, fils, thirty-two of Dr West's patients, and sixteen of Dr Goodhart's, we find that of the total 110 patients, the right leg only was paralysed in thirty-six (a third), the left only in twelve, both legs in nineteen (paraplegia), one or other arm in seventeen (making sixty-five cases of monoplegia or more than half); hemiplegia occurred in twelve (right five, left five, crossed two), facial palsy in seven (all observed by Dr West); while in five cases, three of the limbs, all four, or the muscles of the trunk were paralysed.

Morbid anatomy.—Cornil, in 1863, was the first to record an autopsy in which changes were found in the cord; but the body was that of a woman who had been paralysed when a child, nearly half a century before.

The earliest autopsy after the attack which has hitherto been made was by Royer and Damaschino, in the case of a boy who died of scarlet fever within two months from the onset of the paralysis. The results of this, and of a few other observations made within two years of the attack, are summed up by Erb as follows:—To the naked eye there is generally no perceptible alteration. Sometimes the cord seems rather tough, and its antero-lateral columns are a little shrunken at the level of the lumbar or of the cervical enlargement. Its structure may be slightly blurred. The forepart of the grey matter may be whitish or pink and softened, or even reduced in size; the corresponding motor nerve-roots may be atrophic, grey, and translucent. The microscope reveals an extensive area of morbid change, perhaps an inch or more in length, in this region. It is sometimes confined to one anterior grey cornu, sometimes it involves both of them, according to the distribution of the paralytic symptoms during life. Granule-masses are generally present in abundance; there is nuclear overgrowth, the vessels are dilated and full of blood—in other words, there is an *inflammatory softening*. But the most striking change is a more or less complete disappearance of the large multipolar nerve-cells, many of them that still remain being in various stages of atrophy. The nerve-fibres also have undergone destruction, even to their axis-cylinders. At the periphery of the affected area the nuclei are often massed together in large numbers, so as to form a kind of capsule, but slight diffused lesions are discoverable

throughout the grey matter of a large part of the cord, generally in the whole length of the dorsal region. In the anterior and lateral white columns there is little change to be seen; sometimes a slight degree of sclerosis, thickening of the trabeculæ, atrophy of a few of the nerve-fibres, or a few scattered granule-masses. The anterior roots display all the appearances of "degenerative atrophy."

When many years have elapsed since the onset of the paralysis the appearances are far more marked. The shrinking and atrophy of the anterior part of the cord is now evident on the cut surface, especially when the affection is one-sided, in which case the symmetry of the two halves is lost. The anterior and lateral columns may be obviously grey in tint, and translucent as compared with the posterior columns. The anterior cornu is less deeply coloured by carmine, because the protoplasm and nuclei of the motor cells are gone, but the adjacent white substance is more so because the myelin is gone, and Deiters' cells and even fibrous tissue stain better than normal nerve-fibres. Under the microscope the diseased area in the lumbar or the cervical enlargement is seen to consist almost entirely of a delicate connective tissue, containing an immense number of corpora amylacea, but now no granule-masses. No normal ganglion-cells or nerve-fibres are at this stage to be seen; any remnants of cells are shrunken and pigmented. The anterior cornu often contains the small branched spider-cells of Deiters.

That a local affection of the spinal grey matter should set up pyrexia is remarkable. There may be a question as to whether the myelitis is not at first diffused, and whether it does not clear up and subside throughout the greater part of the cord, while one particular region, to which it becomes limited, undergoes entire destruction.

It has not yet been decided whether the starting-point of the affection is in the multipolar cells or in the neuroglia of the anterior cornua. Charcot insists that the fact of its strict limitation to certain regions of the cord is strongly in favour of the former view; he also says that at some points the cells may be found diseased while the connective tissue remains all but normal. Erb thinks that perhaps both tissues become simultaneously diseased. The muscles are diminished in volume, and their fibres are replaced by fatty or by fibrous tissue.

Ætiology.—With regard to the *causes* of acute atrophic paralysis very little is as yet known. It is far more common in children between one and three years of age than in those who are older, but it sometimes develops itself in infants from six to twelve months old. Duchenne has recorded cases occurring in children of twelve days and one month, and the disorder may occur at any age up to puberty, so that it is not separated by any absolute line of age from the atrophic spinal paralysis of adults.

The two sexes appear to be equally liable to infantile palsy. Whether teething plays any part in its ætiology is very doubtful. Wharton Sinkler, an American observer, met with it much more often between the months of May and September than during the rest of the year, the proportion being forty-seven cases to ten; and this is confirmed by Ross, Gowers, and other observers. In July and August Dr Sinkler recorded seventy-seven cases out of 149, and in the same months Dr W. H. Barlow, of Manchester, forty-eight out of 111. The so-called neuropathic family tendency seems seldom to be present. Duchenne says that he has never seen a case of this affection befalling two children in the same family, and the few cases that have

been published are probably mere coincidences. Those who are attacked are commonly neither rachitic nor scrofulous nor syphilitic, but robust and healthy. Sometimes it is directly set up by a chill, at least Erb says that this has been demonstrated beyond dispute (?). Sometimes it arises during convalescence from some acute disease, such as scarlet fever, modified smallpox, or typhoid fever.

The *diagnosis* is seldom difficult, if one keeps in mind the clinical history and features of the disease. One must remember that other forms of paralysis may occur in childhood; perhaps that which is most likely to cause a mistake is a peripheral paralysis of the brachial plexus from sleeping on the side, or from pressure by a band fastened tightly round the arm. In the case of an infant brought by a person ignorant of the circumstances it may be impossible to come to a positive conclusion.

Prognosis.—So far as is known, anterior cornual myelitis is never fatal, whether in a child or in an adult; but complete recovery is rare. When a child first comes under observation at an advanced stage, with the muscles already wasted, one is apt to think that the issue would have been better had treatment been begun earlier. But if it is placed under treatment from the commencement there is great difficulty in saying how far any improvement that occurs is attributable to the remedial measures that may have been adopted.

Treatment.—Next to keeping the palsied limbs warm and promoting their circulation, the application of galvanism to the spine seems to be the most important thing. The poles must be large, and a current of moderate strength may be passed for one or two minutes at a time. Afterwards the paralysed muscles may be galvanised in turn. Faradisation may also sometimes be useful if the muscles have not lost their susceptibility to induced currents. Even when several years have elapsed one must never hastily conclude that electrical treatment will be fruitless. It now and then happens that a few applications produce extraordinary effects, and often, by persevering for several weeks or even for months, one at length attains considerable success. In one case of the author's the internal administration of strychnia was, beyond dispute, the means of restoring to a child the power of standing. Shampooing and friction with stimulating liniments may sometimes be of service. Dr Angel Money observes that massage well carried out is far more useful than electricity. Nourishing food, cod-liver oil, and tonics are matters of course. For the avoidance of the different forms of contracture recourse must be had to mechanical apparatus. Volkmann says that drawing up of the limb may be prevented by fastening the feet every night on a splint with a flannel roller, and carrying a strip of plaster across to the leg.

Acute atrophic paralysis in an adult develops itself in most respects as in infants. Meyer, of Berlin, is said to have been the first who, in 1868, recorded two cases of this kind after measles. Duchenne, Erb, and many others have since written upon the subject. The disease seems never to set in with epileptiform convulsions; but there is fever of greater or less intensity, with headache, drowsiness, and occasionally delirium. After a single night, or at the end of a few days, one or more of the limbs become paralysed, and sometimes there is a transitory failure of the bladder. There is not the slightest impairment of sensibility, the muscles are perfectly relaxed, and their susceptibility to reflex stimuli is lost. Their

electrical reactions are like those of the same disease in children. The ætiology is equally unknown, but it is much more rare in women than in men. Recovery may either be complete or partial; in the latter case the affected parts become contracted and deformed, but not to the same extent as at an early period of life. Of course, there cannot afterwards be any difference in the length of the limbs on the two sides of the body. In the only marked case which has come under the writer's care, the patient, a healthy railway servant, aged about twenty-five, gradually but completely recovered.

CHRONIC AND SUBACUTE ATROPHIC SPINAL PARALYSIS.*—Within the last few years writers on spinal diseases have recognised as a distinct affection a form of paralysis which was first described by Duchenne in 1849 and 1853 under the name of *paralysie générale spinale antérieure subaigue.* He thought that it was probably due to an atrophy of the cells of the anterior grey cornua; and as recent observations have shown that there is a chronic inflammatory change in this part of the cord, Erb proposes to call the disease *poliomyelitis anterior subacuta et chronica.* Perhaps the most suitable designation is "chronic diffused atrophic paralysis," which at once distinguishes it from the "*acute* atrophic paralysis" already described, and also from the *limited* forms of paralysis which are usually known by the title of "progressive muscular atrophy."

Course.—This disorder generally begins in the lower limbs. The patient first experiences a sense of weakness in one or both of his legs, especially in going upstairs, or if he attempts to walk far. At the end of a few days, or in the course of some weeks, this develops itself into actual paralysis, so that he is obliged to keep his bed. Before long the upper limbs are affected, especially the fingers and wrists. The muscles of the trunk also become powerless, so that he cannot sit up, and has difficulty in coughing or sneezing, and in defæcation.

The paralysed muscles are absolutely lax and flaccid. No reflex movements can be excited in them by irritation of the skin or of the tendons. They very rapidly waste, so that with a measuring tape one can follow the loss of substance in the calves or in the thighs from week to week, until the bones seem to be covered only by the integuments. When electrical tests are applied, typical reaction of degeneration is found to be present. Duchenne long ago discovered that susceptibility to faradic currents is extinguished. Others have shown that they react well to interrupted galvanism, that A.C.C. is more marked than C.C.C., and that the contractions are slow and tonic in character.

So far there is nothing in the symptoms of chronic diffused atrophic paralysis which is distinctive of this affection rather than of myelitis, spreading upwards through the whole substance of the cord from its lower end. What shows that the lesion is limited to the anterior cornua is the absence of anæsthesia, the retention of power over the bladder and rectum, and the fact that there is no tendency to the formation of bedsores. Erb, indeed, says that pains in the back and slight paræsthesia in the limbs are not uncommonly present, and that even before the paralysis has developed itself; but on testing the cutaneous sensibility one finds it either perfect, or only very slightly blunted. At the commencement there may be a little febrile disturbance, with headache and digestive disorder, but these quickly

* Chronic myelopathic atrophic paralysis of adults—Poliomyelitis anterior chronica.

pass off and the patient afterwards feels quite well, and eats, drinks, and sleeps as usual.

The further progress of the disease varies in different cases. Generally it remains for a certain time stationary; that is, it ceases to spread upwards, or to extend to fresh sets of muscles, although those already affected go on wasting. Erb says that sometimes at this period the joints become slightly contracted. But at last, after several weeks, a gradual improvement begins to be observed; the arms regain movement, and afterwards the legs. All this takes place very slowly; months pass before the patient can feed himself, or write, or walk. Sometimes he ultimately becomes as muscular and as active as before, but sometimes some particular muscles remain wasted for the rest of his life; according to Erb this is especially apt to be the case with the peronei. As recovery goes on, the electric contractility of the muscles gradually reappears.

On the other hand, there are cases in which no change for the better occurs, but in which the paralysis extends upwards to affect the face and the tongue and to interfere with deglutition and with respiration. In this way the disease may terminate fatally from one to four years after it commencement. It does not appear that there are any special indications to direct a prognosis at an early period of the case.

Histology.—Up to the present time only two autopsies appear to have been made in which the cord was examined by the modern methods. One was recorded by MM. Cornil and Lépine, the other by Dr Webber.* In each instance the multipolar nerve-cells in the anterior grey cornua had undergone a more or less complete destruction; there were evidences of inflammatory changes in the presence of compound granule-masses, the proliferation of the cells of the neuroglia, the accumulation of nuclei round the blood-vessels, and the like. In the antero-lateral columns there was a certain degree of sclerosis or degeneration of nerve-fibres. The motor nerve-roots and the muscles were in a state of extreme atrophy, so that the morbid anatomy of the disease appears to correspond exactly with what might have been anticipated on theoretical grounds.

With regard to the *ætiology* of chronic diffused atrophic paralysis nothing is as yet known. It is a rare affection, most apt to occur in persons between the ages of thirty and fifty; but in this, while differing from acute atrophic paralysis, it resembles several other spinal affections. It has sometimes been ascribed to cold or to an injury of the back, sometimes to intemperance or to sexual excesses.

The *diagnosis* is, in well-marked cases, easy. It is separated from ascending myelitis by the absence of anæsthesia and of pelvic symptoms; from acute atrophic paralysis of adults by its gradual instead of sudden advent; from progressive muscular atrophy by the paralysis preceding instead of resulting from the muscular atrophy, and by its better prognosis; from multiple peripheral neuritis by the absence of tenderness and also of anæsthesia, and of the peculiar distribution of that affection. Chronic atrophic paralysis closely resembles that which occurs in persons poisoned by lead. Indeed, if the latter is dependent on the same change in the anterior cornua, we ought to enumerate chronic plumbism among the causes of the disease now under consideration. But, as we shall see, there are reasons for believing that lead palsy is due to peripheral neuritis.

The *treatment* of the disease appears to be that of chronic myelitis in

* 'Trans. American Neurological Association,' vol. i, p. 45.

general; the chief remedies being iodide of potassium, ergot, and the application of galvanism to the spine. The paralysis is not always progressive, and recovery has been observed.

PROGRESSIVE MUSCULAR ATROPHY.*—In 1850 a French physician, Aran, described under the name of "*atrophie musculaire progressive*," an affection which he believed had been overlooked by previous writers. Only a few instances had previously been recorded by Sir Charles Bell, Abercrombie, and Romberg. Three years later Cruveilhier wrote upon the same subject, in 1853, when he published his classical case of the athlete Lecomte, whose arms wasted muscle by muscle, then his legs, and finally his intercostal muscles, so that he died from want of power to breathe. The preparation from this case is preserved in the Musée Dupuytren. Sir Wm. Roberts, of Manchester, published a monograph in 1858. Next to infantile palsy, it is the most common of all the diseases described in this chapter, but even this is comparatively rare.

Distribution.—In the large majority of instances the upper limbs are first attacked. Aran found that this was the case in nine among eleven patients, and that in seven of them the right arm was that in which the disease began. The proportion cannot be fixed with accuracy, because it is doubtful whether all the cases in which the wasting is first observed in the legs really belong to the same category. Thus, whereas Duchenne says that he met with only two such cases out of 159, Hammond, of New York, speaks of having had eight in a total of twenty-five. Duchenne himself saw one patient in whom the disease began in the *sacro-lumbales*, and one in whom the *pectorales*, the *trapezii*, and *latissimi dorsi* were wasted before the arms became involved. The apparently capricious way in which the atrophy is sometimes distributed is shown by another of this writer's cases, in which, even at an advanced stage, no muscles of the upper limbs except the *supinatores longi* were attacked. Conversely, Trousseau mentions a patient of Bretonneau's, an old lady, who retained power over none of her muscles save those of the right index finger. She could not speak, but with her finger she picked out of a heap of letters those which she required to form words and sentences, and in this way she made her will.

As a rule progressive muscular atrophy begins in the small muscles of the hand, and especially in the ball of the thumb; before passing to the forearm it commonly spreads from the thenar to the hypothenar muscles, and also to the *lumbricales* and *interossei*. Sometimes it appears first of all in the *deltoid* and other scapular muscles. It is remarkable that when the disease attacks the *trapezius* it always leaves the anterior part of the muscle uninjured; and that the *triceps* usually escapes, even when all the other muscles in the arm have wasted away. The patient's arm then hangs helplessly by his side, he cannot raise it by any muscular effort; if he wishes to lay hold of anything he has to swing it forward with a jerk until his fingers are brought into contact with it. His hand often presents the "griffin" or "bird-claw" deformity (p. 398) from paralysis of the *interossei*. His power of prehension is greatly diminished, especially when the *opponens pollicis* is atrophied. Instead of being able to grasp an object between

* *Synonyms.*—Cruveilhier's paralysis—Wasting palsy—Amyotrophie essentielle or protopathique of Charcot (as distinguished from amyotrophic lateral sclerosis, p. 503)—Poliomyelitis anterior progressiva longissima—Chronic spinal (as distinguished from myopathic) muscular atrophy.

the fingers and the thumb, he has to fix it as well as he can within the hook-like concavity formed by the fingers alone.

Whatever may be the starting-point of the disease, it in most cases soon afterwards shows itself in the corresponding muscles on the other side of the body. But sometimes the symmetry of its distribution is very incomplete; so that, for instance, one forearm and the opposite upper arm may be principally affected. Having spread more or less generally over the upper limbs it at length passes to the neck and to the trunk; the lower limbs almost always remain intact until a very late period. But we have seen that exceptional cases are on record of the atrophy beginning in the legs. The face is seldom or never affected.

Symptoms.—The loss of substance in the muscles is in most cases visible through the integuments, and all the more because the subcutaneous fat disappears, and the skin itself becomes thin. The ball of the thumb is flat, and there is an obvious hollowing of the metacarpal spaces, especially of that which lies between the thumb and the forefinger; or the shoulder has lost its fulness, the bones forming sharp angular prominences; or the normal rounded curves of the forearm are replaced by shallow depressions. But in stout persons the wasting is not always thus easily to be detected by the eye. It is not merely concealed by the overlying fat; there is often an actual new growth of adipose tissue in the interstices of the affected muscles, as in infantile paralysis; and since at the same time a tough fibrous material is present, the part sometimes feels as firm and fleshy as in the natural state. The application of a faradic current may at once clear up all doubt, if the disease is in a sufficiently advanced stage; or a minute portion of muscular tissue may be removed for microscopical examination by Middeldorpff's "harpoon," or by Duchenne's "emporte-pièce."

The weakness in the affected muscles is increased by fatigue, and to a remarkable extent by cold. Some patients tell us that when warm in bed after a night's rest, their hands felt as strong as ever. During the day the hands and fingers often look pale and blue, and they are cold to the touch. Jaccoud and others have taken thermometric observations, from which it appears that the temperature is notably lower on the side on which the muscles are the more wasted; it is said that a difference can sometimes be detected even between the two axillæ. Sometimes there is an excessive secretion of sweat. All these symptoms are referred by Leyden to disturbance of the vaso-motor nerves. In several instances a contracted state of the pupils is recorded as having been noticed.

A symptom on which some writers have laid great stress is the occurrence of transient "fibrillary tremors," or slight quivering movements limited to particular fasciculi of the muscles involved in the disease. They may either be spontaneous, occurring when the part is perfectly at rest, or one may elicit them by giving the skin a smart tap with the finger. All observers now admit that so far from being pathognomonic of any one affection, they may be seen under various circumstances, and even in healthy persons, if carefully looked for. Those which follow taps upon the surface of the muscle are particularly well marked in patients who are emaciated by pulmonary phthisis or any similar disease. But in progressive muscular atrophy, the spontaneous fibrillary contractions sometimes far exceed those which occur under other conditions, so as to produce perceptible movements of the limbs and to attract the notice of the patient, although they are

attended with no pain. It is said, too, that they sometimes afford the earliest indication of the extension of the disease to a fresh group of muscles. Duchenne found fibrillary contractions absent in about a fifth of the cases that came under his observation.

The cutaneous sensibility is altogether intact; there is usually no pain in the affected parts, nor are any sensations of numbness experienced. This, at least, is what Charcot says of that form of the disease which he terms "protopathic," and which alone is now under consideration. Leyden and other writers, while admitting that impairment is slight in comparison with the muscular wasting, have yet described partial anæsthesia as of rather frequent occurrence. But they doubtless included certain other affections which Charcot has since shown to be both clinically and pathologically distinct, and which will be mentioned further on in this chapter. Occasionally severe shooting pains are felt, especially in the early stages of the disease.

Course and event.—It is not in every case that progressive muscular atrophy manifests a tendency to spread from one group of muscles to another. On the contrary, it may remain for many years limited to those muscles which are first attacked by it. But, as we have seen, it often extends from the limbs to the trunk; and then it is very apt to destroy life by interfering with the respiratory movements. One should always carefully observe the condition of the intercostals, and also that of the diaphragm. If the former muscles fail to contract, the upper two thirds of the chest cease to expand, and the act of expiration is proportionately shortened. If the latter is atrophied the epigastric and hypochondriac regions are drawn in during inspiration. In either case the patient has frequently to stop between his words to take breath. He has difficulty in crying out and in singing, and the attempt to cough or to sneeze causes him great distress. An attack of bronchitis is almost inevitably fatal, so that the greatest care must be taken to protect him from exposure to cold. Not infrequently the intercostal muscles and the diaphragm fail simultaneously; and then, as the disease advances, suffocation becomes inevitable. Sometimes, on the other hand, the disease proves fatal by spreading to the muscles of the throat and of the pharynx; the symptoms which are then observed will be presently described under the head of "Progressive Bulbar Paralysis." In not a few instances death occurs from phthisis or pneumonia, or from an accidental attack of enteric fever. The duration of progressive muscular atrophy varies from two or three to as many as twenty years.

Ætiology.—The causes of progressive muscular atrophy are quite uncertain. It occurs chiefly in young adults, seldom or never under its typical form in children (cf. *infra*, p. 514); according to Leyden, the mean age is about thirty-two years. It is far more common in men than in women. Friedreich found only thirty-three women among 209 patients, and Sir Wm. Roberts only fifteen among ninety-nine.

Charcot and many other writers think that the disease is frequently transmitted by inheritance. That such transmission sometimes occurs is indisputable; but it would seem that the majority of the supposed examples have really a different pathology (*infra*, p. 515).

Over-use of the muscles, leading to exhaustion (of them or of the corresponding spinal centres), is often regarded as the cause of the disease, as when it occurs in a bank clerk, in a cobbler, or in a saddler. This would naturally be more common in men, although washerwomen are mentioned

as furnishing examples of the same ætiology. But here, again, confusion may have arisen from the admixture of cases of "writers' cramp" with those of the affection now under consideration, since until recently the two diseases were often included under the vague designation of "scriveners' palsy." Progressive muscular atrophy often occurs in persons who have in no way over-fatigued their muscles, and the relation between the supposed cause and its effect is probably that of accidental coincidence. A certain number of cases follow closely upon measles and other acute diseases, and others again after a longer interval upon syphilis.

Pathology and histology.—The true nature of this affection has only gradually been cleared up. Both Aran and Cruveilhier originally supposed that it was a primary atrophy of the muscles, but the latter altered his opinion when in 1853 he found, in the celebrated case of the rope-dancer Lecomte, that the anterior roots of the spinal nerves were grey and atrophied. The central origin of the disease in the destruction of the large motor ganglion-cells of the anterior cornu of the cord was demonstrated by Lockhart Clarke. In 1873, Friedreich, of Heidelberg, devoted a quarto volume to the support of the myopathic view, and proposed to term the affection "Polymyositis chronica progressiva." His chief arguments were that the spinal lesions which had in certain cases been found were very variable in their nature and in their exact position, and that they might fairly be attributed to the extension of an inflammatory process upwards along the nerves. But about the same time Charcot devoted five of his lectures to this subject, and he has shown beyond dispute not only that the most typical form of progressive muscular atrophy in one or both upper limbs is due to a particular change in the corresponding anterior grey horn or horns, but also that other clinical varieties of the complaint can be assigned to separate and distinct affections of the spinal cord.

Duchenne asserted that in the disease under discussion there is *atrophy without paralysis*. Although he abandoned the myopathic theory of its origin, he continued to maintain that there was no failure of "nervous *motor* action." He thought that the multipolar cells of the anterior cornua did not lose their motor, but only their *trophic* function, and asserted that the loss of power was always proportionate to the degree of wasting, and that any muscular fibres remaining at a particular time would always obey the will, even though they might not succeed in overcoming resistance so as to effect a visible movement. In proof of this doctrine he appealed to the fact that faradisation of the affected muscles would cause contractions after they had undergone extreme wasting, so long as any fibres remained. But Erb subsequently investigated with great care the action of galvanic as well as of faradic currents, and he was always able to detect, in at least some of the affected muscles, a modified (or "middle") form of the reaction of degeneration: the fibres contracted slowly under a powerful galvanic current when they were no longer sensitive to the faradic current, and A.C.C. was greater than C.C.C. The facts that this change cannot be detected in other muscles, and that it is easily overlooked where present, he attributes to the partial and gradual character of the atrophy. The fibres which have undergone degeneration are concealed by the still healthy fibres which lie beside them. So far as a theory can go this seems satisfactory; and it allows us to admit nervous motor paralysis. We may therefore conclude that the most common and typical form of Cruveilhier's palsy is truly an atrophic spinal paralysis,

like infantile palsy, but exceedingly chronic instead of exceedingly acute; and it picks out, not certain muscles of a limb, but certain fasciculi, or perhaps certain fibres of a muscle.

Histologically the morbid process in the paralysed muscles is far from being as simple as it was at one time supposed to be. By the earlier writers on the subject they were described as being in a state of "fatty degeneration," having lost their transverse striation, and being full of drops and granules of oil. Robin, however, found that the granules were often dissolved by acetic acid, and therefore could not be all of a fatty nature; and it is now known that while many of the fibres undergo fatty degeneration like that to which the heart is subject, others become merely reduced in size and thickness while retaining their striation, that others pass into the condition known as "cloudy swelling" and that others again undergo "waxy" degeneration, such as may occur in enteric fever. Another part of the process consists in an increase in the number of the sarcolemma-nuclei; and at the same time the perimysium becomes the seat of a cell-growth, from which are developed the adipose and connective tissue that sometimes gives to the muscles a deceptive appearance of being still well nourished. The several fibres undergo destruction not simultaneously, but in succession. Thus there are all possible degrees of wasting, down to a point at which the microscope reveals not a vestige of the normal striation, nor even an empty sarcolemma-sheath. Muscles so affected, instead of red, are pale grey or yellowish, and at length become converted into mere bands of white fibrous tissue, or shapeless masses of fat lying between their tendons of attachment.

The histological condition of the cord in progressive muscular atrophy is essentially the same as we have seen to exist in the acute atrophic paralysis of children and in the acute or chronic atrophic paralysis of adults. The large motor ganglion-cells of the anterior cornua are found shrunken and often much pigmented; or they have disappeared, and Deiters' cells or corpora amylacea take their place, along with fibrous tissue made up of neuroglia, atrophied nerve-fibres, and obsolete blood-vessels. The blood-vessels become enlarged and thickened, and in extreme cases the whole anterior cornu is obviously shrunken to the naked eye. The pathological process differs from that of other forms of cornual myelitis chiefly by its exceeding chronicity.

It is right to add that the anterior horns are said to have been found unaffected in certain cases which during life answered to the type of progressive muscular atrophy, so that many good authorities still admit a primary atrophy of muscular fasciculi, which leads to loss of power without precedent lesion of the anterior cornua or motor roots. This primary or myopathic atrophy will be described separately (*infra*, pp. 514, 519).

In a large number of cases, sclerosis of the crossed pyramidal tracts is also found.

According to Charcot, distinct lesions of the cord have been included under the designation of progressive muscular atrophy.

1. *Primary progressive muscular atrophy — Primary poliomyelitis anterior longissima.*—In the typical affection of Aran and Cruveilhier, as just described, which Charcot proposes to call *amyotrophie progressive protopathique*, the primary morbid change is atrophy of the multipolar cells of one or both of the anterior grey cornua. The resulting impairment of muscular power

presents those characters of sharp and apparently capricious limitation which have already been detailed, and is accompanied neither by disturbances of sensation nor by spasmodic contractions. Charcot's account of this form of the disease was based upon six or seven autopsies, and it has been since fully confirmed.

2. *Progressive muscular atrophy combined with spastic paraplegia.*—Contrasting with primary muscular atrophy there are other cases which Charcot terms *amyotrophies deutéropathiques*, because in them the change in the anterior cornua is secondary to a lesion of some other part of the cord. Of these he describes the commonest as *sclérose latérale amyotrophique*, consisting in a chronic inflammatory process which begins in the lateral white columns (occupying them symmetrically on each side), and then spreads into the grey matter, principally in the cervical region. Türck, in 1856, appears to have been the first to notice this morbid change occurring independently of any disease in the brain. Charcot says that it is characterised clinically by the presence of paralysis with rigidity of the lower limbs, in addition to the atrophy of muscles in the upper limbs. The spasm in the legs is at first transitory, but afterwards permanent; they generally assume a *position of flexion*, and remain but little wasted. In the arms and hands the muscles undergo excessive atrophy, not one by one, as in primary progressive muscular atrophy, but several at once; the elbow assumes a position of semiflexion and pronation; the wrist is bent; the fingers are closed into the palm of the hand. Charcot further says that the morbid change in the muscles presents inflammatory or irritative characters in a more marked degree than in the "protopathic" form; the connective tissue between the fibres undergoes a still more decided overgrowth, and the nuclei with which it is infiltrated are more numerous. Another peculiarity is that the course of the disease is more rapid; all four limbs become quickly involved; the patient is confined to his bed in a few months and does not live more than from one to three years, the usual cause of death being an extension of the morbid process to the medulla oblongata, with the symptoms of *bulbar paralysis*. This form of progressive muscular atrophy is said by Charcot to be always incurable; those affected by it have been from twenty-six to fifty years old; exposure to cold and damp has sometimes been assigned as its cause. At the Salpêtrière five cases had occurred in which autopsies were made when Charcot wrote.

There is no doubt of the accuracy of these clinical observations of Charcot, and we have already stated that lateral sclerosis affecting the crossed pyramidal tracts in the dorso-lumbar region may often be discovered after death. But it may be that this is a descending secondary sclerosis, and that the primary lesion is the poliomyelitis of the cervical enlargement which produces the atrophic palsy of the arms. This view was taken by Leyden. Dr Gowers believes that lateral sclerosis is frequently, perhaps usually, present when there are spastic symptoms during life, and that it is not secondary to the cornual lesion nor (as Charcot supposed) its cause, but part of the same process. He therefore would draw no sharp line between this second and the first variety, either clinically or pathologically.* Erb and Eichhorst recognise the validity of Charcot's striking account of the affection, and place it provisionally with other forms of spastic paralysis.

* See also cases by Dr Ferrier in the 'Lancet' for 1881, p. 822, and a paper by Friedenreich, of Copenhagen, and Roth, of Moscow, in the 'Transactions of the International Medical Congress' for 1884, vol. iv, pp. 100, 105.

It has been mentioned above as one of the forms of secondary spasmodic paraplegia (483).

3. *Hypertrophic cervical pachymeningitis*, with secondary spastic paralysis and atrophy.—Charcot regards this remarkable affection as another form of *amyotrophie deutéropathique*. As its name implies, it is a chronic thickening of the dura mater, which presents a number of concentric layers, and may fill up the whole vertebral canal. It and the arachnoid adhere firmly to the cord, so as to compress and flatten it, and necessarily surround and press upon those nerve-roots which come off at the level of the lesion, generally belonging to the brachial plexus on each side. This affection, like that last mentioned, is attended with progressive wasting of the muscles of the upper limbs, and with rigidity of the lower limbs. It is distinguished by the circumstance that the ulnar and median nerves are especially involved (the musculo-spiral nerve escaping), so that the wrist assumes a position of extension instead of being flexed. Charcot has observed that the skin often becomes anæsthetic, not only in the arms, but in the upper part of the trunk; and that when the lower limbs become rigid they do not seem to waste. But what is especially characteristic of cervical pachymeningitis is the occurrence of an early stage, lasting two or three months, and accompanied by severe pains in the neck and back of the head, by a sort of rigidity of the cervical muscles, by sensations of numbness and tingling in the upper limbs, and sometimes by bullous eruptions. All of these symptoms are of course due to irritation of the nerve-roots at the seat of the disease. The affection seems to stand to the other atrophic spinal paralyses in the same relation as "compression-paraplegia" to the common forms of myelitis. Perhaps the most important point of all is that it is not always incurable. A woman under Charcot's care, after an illness of five or six years, during which she was for a long time perfectly helpless and confined to her bed, ultimately became able to walk, and could also to some extent make use of her hands. The lesion does not tend to spread to the medulla oblongata, so that the symptoms are seldom complicated by the supervention of bulbar paralysis; but there may at last be loss of power over the bladder and the rectum, and bedsores may form, symptoms which are not observed in other forms of wasting palsy.*

We have had what is probably a case of this form of paralysis in a young man who has lain for nearly three years in Philip Ward. His symptoms were at first those of acute cervical meningitis, perhaps of traumatic origin: these were followed by a period of paralysis with wasting of the arms, and

* In 1868 I recorded in the 'Practitioner' a series of cases of progressive muscular atrophy, one of which would seem to have been an example of hypertrophic cervical pachymeningitis, if reliance can be placed on the facts that rigidity of the lower limbs constituted a prominent symptom, and that the patient, a woman aged thirty-two, recovered. At that time I spoke of the affection as altogether exceptional. It is interesting now to refer to the clinical report, and to find that at an early stage she had complained of severe pains about the elbows, which were doubtless due to irritation of nerve-roots. Moreover, three years previously she had for a time lost power in the second finger of the right hand. I have also reason to believe that a second example of the same affection is afforded by another of my cases, that of G. P. H—, aged twenty-seven, who is recorded as having recovered from a well-marked form of progressive muscular atrophy under treatment by the continuous current. This man was readmitted into the hospital in 1869 with severe cramps and numbness in the arms, tonic extension of the legs, rigidity of the recti muscles of the abdomen, and a sensation of tightness round the waist, as if constricted by a cord. On referring to the notes taken in 1867, I find that at that time he had tingling sensations in the arms and weakness of the lower limbs, so that even then the case deviated to some extent from the typical "Cruveilhier's paralysis."—C. H. F.

then of spastic paraplegia with pelvic symptoms. At the present time (March, 1890) the disease has been long in a chronic state.

4. *Hydromyelia.*—In some instances of what may be called a secondary form of atrophic paralysis, a very obvious lesion has been found, a hollow space occupying the centre of the cord. The first case in which atrophic paralysis of the arms was observed in connection with this curious lesion was recorded by Gull in the 'Guy's Hospital Reports' for 1862. The patient, a journeyman tailor, aged forty-four, had suffered for thirteen months from loss of power in the little and ring fingers of the right hand, and for a shorter time from a similar affection of the corresponding fingers of the left hand. The muscles of the hands had undergone extreme wasting. He caught typhus in the hospital, and died of that disease. In the cervical and upper dorsal regions of the cord the place of the grey matter was taken by a large quadrilateral cavity which was supposed to be a dilated part of the central canal. Since *hydromyelus* has been met with without any spinal symptoms during life, we might doubt whether its presence was not a mere accident. In children suffering from spina bifida, hydromyelus is not uncommon. Since the publication of Gull's case, however, similar ones, attended with like symptoms, have been met with by Schüppel and Hallopeau and Westphal; and it now seems impossible to explain them away. Th. Simon has shown that in reality the cavity is often unconnected with the central canal, which lies in front of it and is no larger than natural. He proposes to apply to such cases, instead of hydromyelus, the term *syringomyelus*, originally invented by Ollivier, though not with the object of conveying this distinction. We have already seen that the development of a solid new growth in the cord may be attended with the formation of a cyst in its interior (p. 451); but the cases now under discussion have not that origin. Clinically, the progressive muscular atrophy due to syringomyelus does not appear to differ from the ordinary protopathic form of the disease.*

5. Secondary (or deuteropathic) progressive muscular atrophy may occur as a complication in cases of *Tabes dorsalis* or *locomotor ataxy;* and also in those of *multiple insular sclerosis*, if the morbid change should happen to involve the anterior cornua and destroy the multipolar cells. It may be associated with bulbar paralysis, but the latter affection is usually secondary.

A *tumour* growing in the substance of the cord, or in the membranes, may sometimes be attended with symptoms of a similar kind. As Erb remarks, it is sometimes impossible to distinguish between a meningeal new growth and cervical pachymeningitis. A woman was admitted to Guy's Hospital in 1878 with atrophic paralysis of certain muscles in the left hand; and she also was liable to exceedingly violent paroxysms of pain in the right shoulder and arm, attended with sudden redness and swelling of the tender parts, evidently due to disturbance of the vaso-motor nerves. She had traces of iritis, and the author inclined to the diagnosis of a syphilitic gumma, growing from the membranes and pressing on the cord in the cervical region. She improved under iodide of potassium.

Diagnosis.—Progressive muscular atrophy must be carefully distinguished from other diseases attended with wasting of muscles.

First among them should perhaps be mentioned various forms of *peripheral paralysis* due to neuritis of the several branches of the brachial plexus, such

* Dr Frederick Taylor collected ten cases, and in his papers in the 'Pathological Transactions' (vols. xxix, p. 21, and xxxv, p. 36) gave a complete account of this singular lesion.

as have been described at p. 396. There is no doubt that cases of this kind have often been mistaken for those of Cruveilhier's palsy; but a careful observer will generally recognise the limitation of the affection to the area of distribution of particular nerves; and all doubt will be removed by the application of galvanic and faradic currents, which will reveal a far more marked alteration of the normal electrical reactions than is ever seen in progressive muscular atrophy. Moreover, in peripheral neuritis there is almost always anæsthesia, and usually local tenderness.

The same tests will distinguish ordinary cases of *lead paralysis*, even when the history of the patient, the line on the gums, and the other poisonous effects of the metal are not of themselves sufficient to prevent hesitation as to the diagnosis. For the peculiarities of the reaction of degeneration are well marked; whereas in progressive muscular atrophy they are either imperfect (p. 500) or the muscles continue to respond to faradism as well as to galvanism so long as there is any muscle left to contract; the reason probably being that the motor nerves, trophic cells, and muscle-fibres with their end plates all undergo very slow and equal atrophy, and healthy muscle is not left with damaged anterior cornua and degenerated nerves, as is the case in lead palsy.*

The diagnosis from *chronic atrophic spinal paralysis* apart from lead (p. 495) rests on the facts that, in the latter, paralysis precedes atrophy, instead of going with it, and that instead of the reaction of degeneration occurring only in the "middle" or qualitative form, or only towards the close of the disease, or not at all, it is present in its typical form just as in infantile palsy.

Another possible error is to mistake for progressive muscular atrophy the diffused wasting of the muscles, attended with great helplessness and loss of power, which is a result of protracted *osteo-arthritis*. The hollowing of the interosseous spaces and of the ball of the thumb may be very striking in cases of this kind.

French writers describe under the name of *marasme essentiel*, an atrophic affection which they say occurs in hypochondriacal patients, who gradually assume the appearance of living skeletons. It corresponds with the remarkable case of emaciation in a man who was cured by Weir Mitchell's massage treatment, published by Drs Playfair and Brunton. There is, however, no true paralysis in these cases.

Prognosis.—The natural course of progressive muscular atrophy is gradual but fatal. Its tendency is slowly but surely to spread from one muscle to another until those of respiration are involved. Occasionally its course is arrested without apparent cause, and the atrophied muscles remain like those of a withered limb after infantile palsy.

Treatment.—Experience has shown that drugs are of little value in this disease, though Dr Gowers thinks that arsenic and strychnia are sometimes of service. Neither nitrate of silver, phosphorus, nor iodide of potassium can restore the wasted muscles, or prevent further extension of the disease.

* I have seen a few instances in which, although it was known that the poison had been absorbed to some extent, opinions yet differed as to whether this fact would satisfactorily account for the symptoms, which seemed to be too severe, or too little amenable to treatment, to be caused by lead. Two such cases I published in the 'Practitioner' (1868), under the name of progressive muscular atrophy. I am bound to say that now, on reading them over, I think that the view then taken was wrong: they were cases of plumbism.—C. H. F.

There is considerable evidence of the value of electricity. Faradisation of the affected parts was strongly recommended by Duchenne. He advised the application of currents of moderate intensity, with not too frequent intermissions, and for a few minutes only at a time, so as not to fatigue the fibres remaining undestroyed; he particularly insisted on the importance of including in the treatment any important muscles, such as the diaphragm, the intercostals, and the deltoids when they are first threatened by the disease, and before they are wasted. In the case of a man named Bonnard, who had lost many muscles of his trunk, and who was beginning to suffer from dyspnœa, so that he could scarcely walk a few steps without stopping to take breath, faradisation of the phrenic nerves, repeated three or four times a week, was of great service, enabling him to walk considerable distances and to go upstairs without fatigue. A similar treatment, applied to certain muscles of the arms which were wasted, restored their functions, so that at the end of six months he was again able to support his family by his exertions. And he went on for some years without the disease advancing further.

Remak advocated the use of the galvanic current. His method was to place the positive pole in front of one mastoid process, and the negative pole on the opposite side of the neck, near the spinous processes of the vertebræ, not higher than the fifth cervical. This, he found, would often produce contractions in the fingers or other paralysed parts.

All observers admit that in not a few cases both these plans of treatment utterly fail. They may, however, be tried in succession; and it is worth while to persevere with them, even when they seem at first to be doing no good, because sometimes good results have been attained after several months of electrical treatment.

Dr Ross believes that all drugs are useless, and that galvanism is the most efficient remedy for progressive muscular atrophy. But Dr Gowers finds that "the most sedulous and skilful use of electricity, voltaic or faradic, fails, as a rule, to produce any effect on the course of the disease." He is equally incredulous of the asserted benefits of *massage*, which are "usually inappreciable," and of *balnéothérapie*. Even when the disease follows syphilis he finds mercury useless. "The disease is one in which it is not easy to do good and not difficult to do harm."

Early in the disease the affected parts should be rested as much as possible. In one of the author's cases the forearms were wrapped in cotton-wool and placed in splints, and after a week the patient was found to have much more power in his hands. But in the more advanced stages methodical exercise of the wasted muscles appears to be sometimes useful.

PROGRESSIVE BULBAR PARALYSIS.*—In 1860, Duchenne gave a clinical description of a form of progressive paralysis of the tongue, palate, and lips, which had previously received no systematic recognition from writers in medicine, although Trousseau, as far back as 1841, had noted the peculiar symptoms presented by a well-marked case occurring in the Prince de la Moskowa. The disease has now become well known in England, and is often termed labio-glosso-laryngeal paralysis, after Trousseau and Duchenne;

* *Synonyms.*—Labio-glosso-laryngeal paralysis — Glosso-labio-pharyngeal paralysis—Duchenne's paralysis—Progressive muscular atrophy of the tongue, palate and lips—Atrophic bulbar paralysis (Leyden).

but a shorter and better name is that of "progressive bulbar paralysis," which was originally suggested by Wachsmuth in 1864. As Kussmaul has remarked, it might be called "progressive paralysis of the bulbar nuclei;" for the morbid change does not involve that part of the bulb (*i. e.* medulla oblongata) which transmits the motor and sensory strands for the limbs and the body generally, but is confined to the grey centres for certain of the cranial nerves on the floor of the fourth ventricle.

Course and symptoms.—As a rule, bulbar paralysis begins insidiously. The earliest symptoms are commonly subjective,—a feeling of pressure at the back of the neck and head, a little giddiness, a sense of constriction round the throat or chest, slight discomfort in talking, as if the tongue were heavy and its movements laboured, or a tired feeling after speaking. Krishaber has stated that in two cases he discovered a loss of reflex irritability in the pharynx and larynx some months before any signs of paralysis made their appearance. Sometimes the palate is affected before the tongue, or the disease begins in the lips: in the former case the speech acquires a "nasal" quality, and swallowing seems to require an unusual effort; in the latter the expression of the face about the mouth becomes altered, or there may be difficulty in the utterance of certain letters, as though (to use a phrase of Duchenne's) the lips were half paralysed by cold.

Sometimes, however, the commencement of the disease appears to be sudden. Kussmaul, in one of the clinical lectures published by Volkmann, relates that a patient of his, a Catholic priest, found one day, while preaching, that his mouth was distorted and that he had a difficulty in speaking. He was able to finish his sermon, but from that time he felt "a heaviness of the tongue." For a week previously he had suffered from pains in the back, but he had had no giddiness. Dysphagia soon set in, and within six months the case became one of confirmed bulbar paralysis, with loss of power in the arms and wasting of the small muscles of the hands. It was ascertained at the autopsy that there was no hæmorrhage into the pons or the medulla oblongata; and this, as well as the progressive character of the complaint, distinguishes it from certain cases of Wilks, of hæmorrhage in the bulb producing symptoms of paralysis to which we shall presently refer (p. 513). In a woman whose case is recorded by Leyden the first symptom was a sudden attack of dyspnœa, lasting five minutes; a few days afterwards she noticed a difficulty in moving the tongue when she spoke or ate.

In fully developed cases the tongue is generally the part in which the loss of power is most obvious. It lies flaccid in the floor of the mouth; the patient can neither bend it laterally, nor raise it against the palate, nor hollow its centre; and he may be unable to protrude it beyond the teeth. Scarcely less marked is the paralysis of the lips. The mouth remains open, and with its angles drawn wide apart; the naso-labial furrows are deepened, the lower lip hangs away from the gum. The patient cannot whistle or blow out a candle, or kiss. What is most remarkable is that although facial muscles supplied by the lower branches of the *portio dura* are thus affected on both sides in every case, those to which the upper branches of the same nerve are distributed as constantly escape. The orbicularis palpebrarum and the occipito-frontalis act as well as ever. The countenance thus acquires a curiously contrasted expression: the eyes are full of life, while the mouth is fixed, sad, and gloomy.

On the other hand, the paralysis of the palate is not indicated by any obvious change in its form. The uvula hangs in its ordinary place; and

Duchenne says that he always found that touching the fauces caused the usual reflex movements. With the laryngoscope the vocal cords may in advanced cases be seen to be more or less completely paralysed.

Several important functions are impaired in ways which are somewhat complicated, and demand careful study. Thus the defect of speech appears to vary with the part which becomes earliest paralysed. According to Kussmaul, if the lips suffer first, O and U are the vowels which the patient experiences most difficulty in uttering; if the tongue, I is sooner lost. A is always retained longer than any of the others.* Among consonants, loss of power in the tongue renders the patient first unable to utter TH, R and SH; next S, L, K, G, T; afterwards D and N. Paralysis of the lips prevents the formation of P and F, then of B and M, ultimately of V. Paralysis of the palate gives to the speech a nasal twang, and it specially prevents the formation of the lip-sounds B and P, because it allows so much of the air to escape through the nose; the proof of this being, as Duchenne pointed out, that closing the nostrils may enable these letters to be sounded. So far the affection of speech is one which merely concerns articulation, and may be called "anarthria," in distinction from the "aphasia" that depends upon lesions in the left side of the brain, and the "aphonia" that is caused by loss of power in the larynx. But in bulbar paralysis, after a time, the vocal cords also lose their functions; and the voice becomes extinguished.

Another set of movements which are interfered with in progressive bulbar paralysis are those which are concerned in the reception of food into the mouth, and its transmission backwards into the œsophagus. During mastication it collects inside the cheek, not only when the buccinator is paralysed, but (even apart from this) because the tongue cannot properly dislodge it. Very often the patient helps himself with the fingers of both hands, supporting the floor of the mouth or the cheeks, or pushing the half-chewed food into the proper position. Then, again, the tongue cannot roll up the softened pulpy material into morsels for swallowing, nor carry them into the pharynx. Loose fragments are constantly dropping out of the open mouth into the plate or upon the patient's clothes. Other pieces collect about the root of the tongue, or in the grooves by the side of the epiglottis. The attempts to swallow them succeed very imperfectly—some pass up into the pharynx or through the nose, others enter the larynx and set up a choking cough; they may even accumulate in the fauces to such an extent as to interfere with the passage of air and to produce sudden death. It depends upon circumstances whether the patient finds most difficulty in dealing with solids or with liquids. If the principal defect is a weakness in the tongue and in the muscles of mastication, he requires to have all his food reduced to a semi-fluid state; but when there is paralysis of the parts concerned in closing the larynx during deglutition, he can often dispose of solid masses better than of liquids, being unable to prevent the latter from trickling down into the air-passages. The inability to swallow gives to the disease another peculiarity in the circumstance that the saliva keeps running out of the mouth; such patients keep a handkerchief constantly held below

* These vowels must be pronounced in the Italian way: U=OO (in *fool*), I=E (in *feel*), A=Ah (in *father*). The two English sounds represented by the letters Th are among the first to disappear in cases in which the tongue is affected. Kussmaul's statements correspond closely with what might have been anticipated from theoretical considerations, of which an admirable account will be found in a paper by Dr Bristowe in the first volume of the 'St Thomas's Hospital Reports.'

the chin, and, as Wilks remarks, this often at the first glance enables one to guess what is the matter with them. The secretion itself is sometimes viscid, sometimes watery. It seems so abundant as naturally to suggest that it is formed in excess, and in one instance Schultz is said to have estimated that there were six or eight times as much of it as would have been poured out under normal conditions. Kussmaul, however, found no such increase in a case in which he determined its quantity. Sometimes the masticatory muscles become at length involved in the paralysis; the patient is then unable to move the lower jaw from side to side, nor can he close the mouth firmly.

Generally the respiration is not obviously affected at an early stage of the disease. Later on dyspnœa often becomes a marked symptom, and on stripping the patient one may find that the respiratory movements of the chest walls are very shallow. In some cases, however, distress of breathing and a constant craving for air are said to have been present, although the diaphragm and the thoracic muscles were still vigorous. Kussmaul cites the written statement of a woman under his care who was in great dread of gaping, because "she was obliged to groan and strain in order to get rid of the air and then breathe more freely." He follows Duchenne in attributing such symptoms to paralysis of the bronchial muscles. There is generally inability to sneeze, to cough, to hawk up phlegm, and to blow the nose; the patient sometimes complains that he is no longer able to smoke. Towards the last, paroxysms often occur, attended with a rapid pulse; these are supposed to depend upon paralysis of the vagi.

Among the symptoms which have been noticed in some exceptional cases may be mentioned slight deafness, noises in the ears, ptosis, paralytic affections of the ocular muscles, numbness and anæsthesia of the face or tongue. Physiological considerations have led naturally to a search for sugar in the urine; but this appears to be always found normal.

The higher cerebral functions remain undisturbed, the patient sleeps well, his intelligence and memory are perfect. The movements of the body and limbs are generally free and active, except towards the last, when there is emaciation from want of food and extreme weakness.

Pathology.—Although, as just stated, the great motor paths through the bulb and the pons escape, it nevertheless frequently happens that there is associated with bulbar paralysis an affection of the upper (or more rarely of the lower) limbs, which agrees in all respects with what has already been described as Progressive Muscular Atrophy. Sometimes one, sometimes the other of these two diseases is the first to develop itself. Duchenne drew a sharp distinction between the two diseases. In labio-glosso-laryngeal paralysis he said there was paralysis without atrophy; in progressive muscular atrophy there was atrophy without paralysis, and certain cases in which he found the tongue wasted were regarded by him as examples of a separate malady, a true progressive muscular atrophy involving that organ. But we have seen that the tendency of recent investigations into "Cruveilhier's palsy" is to show that it is a true spinal paralysis. Moveover, there seems to be no satisfactory proof that, after death from progressive bulbar paralysis, the muscles have ever been examined microscopically and found to be all in a healthy state. Charcot once discovered degenerative atrophy in a tongue which during life had appeared smooth and of natural size, so that it is clear that nothing but pathological evidence can be conclusive. In many cases the fleshy substance of the tongue, and even that

of the lips and palate, is obviously pale, of a yellow or greyish-red colour; and it is streaked with fat or more or less completely converted into a mass of fatty connective tissue.

Thus at the present time the opinion of all the most competent authorities is that progressive bulbar paralysis is pathologically identical with progressive muscular atrophy, differing merely in the circumstance that it affects a particular set of nerve-nuclei in the bulb instead of those in the cord. It is admitted that in the earlier stages the tongue is often not obviously reduced in size, but in advanced cases it is described as being soft, small, wrinkled on the surface, and incessantly agitated by a fibrillary tremor. The lips also become thin and sharp edged; their muscular substance quivers, and the skin over them is marked with minute furrows. In the palate, as might be anticipated, wasting of the muscles is not discoverable, at least during life. It is allowed that there is no absolute correspondence between the degree of the paralysis and that of the atrophy.

The results which have been attained by testing the affected muscles with electricity appear to accord with these statements. The earlier investigators described the faradic contractility as normal; but several German observers have since found it lowered or even extinguished; and with galvanic currents, Erb (as well as Kussmaul) has recently detected the reaction of degeneration in a perfectly characteristic form. The mistake seems to have arisen from the stimulus having been applied to the motor nerves instead of to the muscles themselves. Lastly, atrophy of the motor cells which form the nuclei of the hypoglossal and other motor nerves in the bulb has now been repeatedly observed after death from bulbar paralysis; and this agrees histologically with the lesions of the anterior cornua seen in Cruveilhier's palsy. The bulb after all is but the *medulla spinalis oblongata*, and the grey matter of the floor of the fourth ventricle is formed by the anterior cornua laid open and separated, so that the seat of each disease is serially homologous.

Histology.—Kussmaul cites eight cases of progressive bulbar paralysis, in each of which a complete microscopical examination was made. In general no marked change is seen by the naked eye in the fresh medulla oblongata; but it is said that sometimes a little want of symmetry in the two halves of the floor of the fourth ventricle has been detected, or a slight shrinking; or that this part has appeared discoloured and reddish grey; or that its texture, when cut into, has looked blurred; or that its consistency has been greater or less than natural. One thing, however, is very obvious, even to the naked eye, namely, an extreme degree of atrophy of the nerve-roots arising from this part of the cerebro-spinal axis. It is especially conspicuous in the hypoglossal and the facial nerves; but it is generally plainly visible also in the three divisions of the eighth nerve on each side, and sometimes in the sixth, and in the motor portion of the fifth. The roots in question are grey and transparent, and exceedingly reduced in size.

In stained sections of the hardened medulla oblongata the multipolar cells in certain nuclei are uniformly found to have undergone degenerative changes. Their colour is darker than natural, being deep yellow or yellowish brown; they are often shrunken; their prolongations may be indistinct or may have quite disappeared. They seem to be reduced in number. In one case Charcot and Joffroy came to the conclusion that the hypoglossal nucleus contained only one tenth or one twelfth part of the cells which would have been present in it in a healthy bulb. French histologists appear

not to have recognised any marked change in the neuroglia, but in Germany Leyden in 1870, and Maier, and other observers since, have found it increased in quantity, filamentous, and containing stellate cells; in other words, presenting appearances like those which characterise myelitis going on to sclerosis. The nerve-fibres undergo atrophy. The parts in which these changes are most constantly seen are the nuclei of the hypoglossal, the vagus, and the facial nerves. As regards the last-mentioned nerve, indeed, the symptoms of bulbar paralysis point to the conclusion that only a part of its nucleus is affected; and this accords well with Lockhart Clarke's statement that its roots arise in two separate masses of grey matter; but it does not appear that the obvious pathological application of his observations has been yet traced out in detail. The nucleus of the glosso-pharyngeal nerve escaped the morbid process in a case recorded by Duchenne and Joffroy. The sensory nucleus of the fifth and that of the auditory nerve have been constantly found intact. The olivary bodies have sometimes presented degenerative changes, but more often they have been in a normal state.

Ætiology.—With regard to the causes of bulbar paralysis nothing is certainly known.* It scarcely ever occurs in persons under thirty, and appears absolutely to increase in frequency as age advances up to the seventieth year. It is more common in men than in women—thirty-four cases in fifty-three collected by Kussmaul.

The few cases that have been recorded in young persons have presented peculiar features, and their pathology is still undetermined.

Diagnosis.—This at the commencement of the disease requires considerable acumen; one might easily make light of the early symptoms, and so justly forfeit the confidence of the patient. Even when they are fully developed, one must avoid a hasty conclusion, for the lips and the tongue may be paralysed by various affections, beside that which constitutes the disease described by Duchenne. What characterises it is the absence of additional symptoms which belong to them.

Wilks has pointed out that a condition precisely like that which belongs to progressive bulbar paralysis may be suddenly developed as the result of a circumscribed effusion of blood into the lower part of the pons. He relates in the 'Guy's Hospital Reports' two cases, in one of which an old brownish cyst was found at that spot after death. The same author has seen the disease simulated by hysteria; other observers have recorded cases due to syphilis which have been cured by iodide of potassium; and tumours growing near the bulb may cause similar symptoms.

Prognosis.—It seems probable that the very few recorded instances in which recovery has taken place from "bulbar paralysis" have been essentially different from those described by Duchenne.

Genuine cases which depend upon a progressive change in the bulbar nuclei appear always to end fatally. This was Trousseau's verdict, and all later experience confirms it. Their duration is generally from one to three years; but it may be as long as five years. Sometimes the patient is choked unexpectedly by a mass of food which cannot be propelled beyond

* Erb speaks confidently of its being sometimes caused by cold, and Kussmaul relates a case in which the patient traced it to a cold caught while he was at work in the fields; he was attacked with headache and pain in the neck, and a week later he was conscious of difficulty in swallowing and in speaking. Among other conditions which have been supposed to give rise to it are excessive smoking, over-exertion in playing wind-instruments, syphilis, and falls producing concussion of the medulla oblongata. In one of Trousseau's cases it began during convalescence from a febrile attack.

the entrance into the larynx; of this an instance occurred at Guy's Hospital in 1865. Sometimes death is brought about by an attack of syncope, sometimes by a paroxysm of dyspnœa. Kussmaul remarks that such seizures are particularly apt to happen after exertion of some kind, but that they not infrequently occur at night when the patient is in bed. In other cases exhaustion and emaciation gradually lead to a fatal termination; or pulmonary phthisis may develop itself; or acute pneumonia, consequent upon the admission of food into the air-passages during the act of deglutition.

Treatment.—It is doubtful whether any benefit results from the therapeutic measures yet tried. Kussmaul recommends dry cupping at the nape of the neck in early cases, and the use of shower baths. Among drugs he thinks the nitrate of silver most likely to be serviceable. He has seen temporary benefit from faradisation of the palate and tongue; and he mentions two cases in which striking results were for a time attained by the use of strong galvanic currents passed through the neck and spine. One of his patients, the priest, mentioned above, who had been unable to get his tongue out between his teeth, could, after being galvanised, protrude it beyond his lips; his speech became more distinct and his deglutition easier. After four or five weeks, however, the improvement ceased. Specially applicable to progressive bulbar paralysis is, perhaps, Schulze's method of inducing the act of deglutition by galvanism. It consists in fixing the positive pole upon the nape of the neck, and then rapidly moving the negative pole downwards over the side of the larynx. This procedure may be repeated at short intervals several times during four or five minutes. In the first instance a current from six to eight cells should be tried; but to produce the desired result a large number of elements are often required.

When the patient cannot swallow food at all, or seems likely to be choked in the attempt, a tube must be passed into the stomach; but this procedure often has to be abandoned on account of the irritation excited by it. Nutrient enemata then afford the only means of sustaining life for a time, unless recourse is had to gastrostomy. In one case at Guy's Hospital the trachea was opened when danger was apprehended from frequent attacks of dyspnœa; and the result was that they ceased, although of course the other symptoms remained.

Acute bulbar paralysis—myelitis bulbi acuta focalis.—The remarkable malady just described is pathologically an example of atrophy of the ganglion-cells of the motor tract; comparable with the similar anatomical condition which precedes progressive muscular atrophy, the latter affects the anterior cornua of the medulla spinalis, the former the corresponding grey nuclei in the medulla oblongata. A few cases have also been recorded of acute paralysis of the muscles, supplied from the bulb which similarly corresponds to acute atrophic spinal paralysis from acute anterior cornual myelitis. Three examples are cited by Erb, all of which were observed by Leyden. In one case a patch of softening with numerous capillary extravasations of blood was plainly visible in the pyramids and in the olivary bodies at the autopsy; in the others no lesion was discovered until the parts had been hardened, when the microscope revealed inflammatory changes of the most marked kind. Each patient had been taken ill rather suddenly, and had died in from four to ten days. The symptoms varied considerably, since they depended upon the exact seat of the morbid process in a part of the

nervous system where so many important centres are gathered into a narrow space. Chief among them were dysphagia, headache, giddiness, vomiting or severe hiccough, more or less impairment of speech, irregular, rapid, or interrupted breathing, a quick, feeble and intermittent pulse, partial or complete paralysis of the tongue, formication and pains in the limbs. There was no failure of consciousness, nothing at all resembling an apoplectic seizure. Depression and collapse quickly set in, and the fatal issue was brought about by paralysis of the respiratory muscles, with distress of breathing and lividity.

The *diagnosis* of the seat of the disease seems not to be difficult; but it is not easy to exclude the possibility of embolism of the basilar artery or of the vertebral arteries or their branches, or of a minute spot of hæmorrhage, or even of a rapidly-developed compression of the medulla oblongata by some disease in its neighbourhood. Possibly such cases need not invariably prove fatal, since recovery from ordinary myelitis is not unknown.

A case which seems to have been of this kind occurred in Guy's Hospital in 1874, in a man aged forty-five. It proved fatal in about ten days. The central part of the pons appeared softened; but after preparation in chromic acid no decided morbid changes were made out.

Hæmorrhage, embolism, tubercular and other tumours of the bulb, have been recorded, with symptoms resembling those of focal myelitis affecting the same region.

PROGRESSIVE MUSCULAR ATROPHY OF YOUTH.—*a. The early form of Duchenne.*—According to Duchenne, progressive muscular atrophy is not so rare as is supposed in children, and when it occurs presents certain peculiarities in its symptoms and course. It begins in the lips, which become thick and cannot be brought together. If the child smiles, the angles of the mouth are drawn far apart, and the cheeks are flattened by the action of the buccinator muscles. The articulation of labial letters and of the vowel *o* is impaired. It is almost always between the fifth and the seventh year that this form of the affection first appears; but at that time it often attracts little notice from the parents, although the reality of the morbid change is at once made apparent if the orbicularis oris and the other muscles are tested by faradic currents, when they are found to have lost their contractility. About the eleventh or twelfth year the muscles of the shoulders and arms begin to waste, and then medical advice is first sought. Later still the muscles of the trunk and those of the lower limbs are attacked in their turn, but the hands escape.

This form of disease is extremely rare; but Duchenne, whose first cases were recorded in 1855, said in 1872 that he had observed no fewer than twenty. One fact which would tend to show that the progressive muscular atrophy of childhood is distinct from the most common forms of wasting paralysis in adults is that it very often occurs in two or more brothers and sisters; but a curious circumstance is that the father of the first two children in whom Duchenne recognised its peculiar characters was afterwards, at the age of forty-eight, attacked with typical "Cruveilhier's paralysis," affecting first the shoulders and arms, but ultimately the lower limbs; he also stated that his father had died of a similar complaint. Whether this was anything more than an accidental coincidence it is difficult to say.

Duchenne's description was written in 1855, but no one appears to have observed similar cases until Landouzy and Déjérine published several in 1874 and one, with an autopsy, in 1885. Barsickow's series of cases of hereditary muscular atrophy, published in 1872, are of a similar clinical type. Westphal, E. Remak, and other writers in France and Germany, have published a few cases since. The muscles of the face are not exempt, and girls as well as boys are affected. The cord and bulb have been found unaffected. If the seat of the disease is in the nerves, it is a form of Peripheral Neuritis affecting the facial and other motor nerves; but in most cases it appears to be of primary muscular origin.

β. *Erb's juvenile hereditary form.**—A clinically distinct "juvenile form" of progressive muscular atrophy has been described by Erb ('Deutsches Archiv f. klin. Med.,' 1884). It usually begins at puberty. The muscles of the shoulder are more affected than those of the hands, and the legs are not infrequently attacked. The face and hands escape. These cases, like Duchenne's above noted, are marked by a *hereditary* character. There are no fibrillary contractions, no reaction of degeneration even of the "middle" or imperfect kind, and *post mortem* the anterior cornua have been found intact in two cases by Friedreich. Occasionally the deltoid or other paralysed muscles hypertrophy—which connects this form with the pseudo-hypertrophic atrophy to be next described.

γ. Dr Tooth has collected the previously published cases of hereditary atrophic paralysis, and added four new ones (Thesis, 1886). Of 30 in all, he finds that 8 occurred between one and five years of age, 10 between five and ten, and 18 between ten and twenty, while only 3 patients were older—twenty-five, thirty-seven,and forty-six; 28 were males and 16 females, so that the disproportion between the sexes was much less than in Cruveilhier's muscular atrophy. Grouped in families, there were 17 instances of more than one case in a family, and only 12 isolated.

In one group the lower extremities were first affected, and particularly the *peroneal* muscles. The extensors and gastrocnemii shared in the paralysis, and the hands and forearms followed. Fibrillary tremors and marked reaction of degeneration were usually present. ('St Barth. Hosp. Rep.,' 1889; see also 'Lond. Med. Rec.' for October of the same year, p. 430.)

It appears from the clinical features, as well as from the anatomical results of Friedreich's two cases, that the lesion is not central, but either a Peripheral Neuritis or primary (myopathic) muscular atrophy. In a case in Virchow's ('Archiv,' 1855) there was sclerosis of the posterior cornua and root-zones.

δ. Meryon's remarkable cases of *hereditary muscular atrophy* described in 1852, may not improbably belong to this same clinical group. They have, however, been generally appropriated as examples of the following disease, and will be again referred to (p. 517).

PSEUDO-HYPERTROPHIC PARALYSIS.†—In 1861, Duchenne recorded in the second edition of his 'Electrisation Localisée' the case of a boy whose legs were so weak that he could scarcely stand, while the muscles of his calves and hips looked like those of an athlete. Seven years later the same fertile author wrote a detailed paper on the disease in question.

* *Syn.*—Dystrophia musculorum progressiva juvenilis (Erb).—Myopathic atrophy of adolescents.

† *Syn.*—Myopathic atrophy with fatty overgrowth—Myosclerosis—Progressive muscular sclerosis—Lipomatosis musculorum luxurians.

In the meantime cases had been noticed by a few German observers. There was one in 1863 in Oppolzer's wards at Vienna; and another, which came under Griesinger's notice in 1864, gave Billroth the opportunity of excising a piece of the deltoid muscle and of proving that there was no real but only an apparent hypertrophy; for it consisted almost entirely of adipose and fibrous tissue, while the muscular fibres themselves were unaltered. Duchenne, in 1865, made similar observations in one of his cases with the aid of his "emporte-pièce." He therefore proposed to term the disease *paralysie myosclérosique*. Dr Gowers' monograph, published in 1879, contained all the information obtained up to that date, and little has been added since.

Histology.—The substance of the enlarged muscles has a whitish-yellow colour, with only a faint reddish tint. There is still a linear arrangement of the fibres, and in extreme cases this alone distinguishes it from the subcutaneous adipose tissue. The fat sometimes extends into the tendons, so that during life they seem to have been encroached upon by the fleshy bellies of the muscles. Occasionally, on the other hand, fibrous tissue only and no fat has been found between the muscular fibres; and in the earlier stages of the disease, this new tissue has been found full of nuclei or spindle-cells. The muscular fibres seem to become greatly reduced in number by a process of simple atrophy, which at last leaves only the collapsed sarcolemma-sheaths. Those fibres which remain are not always completely unaltered, as described by Griesinger. Duchenne described their transverse striation as unusually faint. Other observers have seen some which were striated longitudinally, some which were translucent or "waxy," and some which were in a state of granular or fatty degeneration. Some fibres again are truly hypertrophied, so as to be two or three times as thick as normal; a fact first observed by Cohnheim.

True muscular hypertrophy.—Apart from the physiological hypertrophy of health, a few cases have been described—by Auerbach, Berger, and Friedreich—in which the muscles of the limbs, particularly the arms, have greatly increased in size without increase or with diminution of contractile power. When a minute portion is extracted it is found that the individual fibres are increased in diameter, without interstitial fibrous or fatty overgrowth. Though it is nearly twenty years since the first case was recorded, the pathology of this rare affection is quite unknown.

Course.—The enlargement of the muscles is not present at all stages of pseudo-hypertrophic paralysis. There is an early period during which the only symptom is an impairment of power in the lower limbs. The child—for the affection almost always begins in childhood—is noticed to totter in walking, and to be apt to fall; he has difficulty in getting on to his feet, and is particularly awkward in going upstairs; when he tries to sit down he falls into the chair. In many cases the commencement of the disease occurs before the little patient has learned to walk. At first the parents think that the child is only backward, as so many rachitic children are, but at length they see that there is something more seriously wrong.

When, at the end of a few months or a year from the beginning of the paralysis, the change in the muscles is discoverable, its extent and degree vary widely in different cases. The calves are often affected alone; next in liability to undergo enlargement are the masses of the *erector spinæ* in the loins, the *glutæi*, the *deltoids*, and the *infra spinati*. The *glutæus medius* usually escapes. The muscles of the thigh, the *latissimus dorsi*, the lower

part of the *pectoralis* and *serratus magnus* are more often reduced in size, so as to afford a strange contrast. But sometimes the whole of the trunk and every part of the limbs displays an exaggeration of contour which leaves far behind that of the Farnese Hercules, as Duchenne shows by comparing a sketch of that ancient statue with portraits of a patient of his, a boy ten years old. The enlarged muscles are generally firm and elastic, and when they are brought into action they harden so that it is difficult to believe that they do not consist wholly of contractile elements.

When a child affected with pseudo-hypertrophic paralysis stands up, his attitude is characteristic. The abdomen is pushed forwards, and the hollow of the lumbar vertebræ is greatly exaggerated. The nates project backwards; but the shoulders are thrown further back still, so that a line dropt from the upper dorsal spines falls behind the sacrum. The legs are separated widely from one another. If an attempt is made to straighten the back the child at once falls down. When he walks, he balances the body from side to side at every step, with a "waddling" gait. He cannot rise from the sitting posture without the use of his hands, and the way in which he uses them is very characteristic. He places both hands upon his knees, and gradually pushes up his body into the erect posture by moving his hands from his knees to his groin. This manœuvre, which has been not inaptly called "climbing up the thighs," is well represented by sketches in Dr Gowers' work on 'Diseases of the Cord' (p. 391), and by photographs in Dr Ross's work (vol. i, p. 996).

The susceptibility of the affected muscles to faradic currents is sometimes normal, but in other cases it is considerably lowered. This appears to depend solely on the degree of atrophy of muscular fibres. There is no reaction of degeneration. As with all the atrophic disorders of muscles described in this chapter, pelvic symptoms are absent, and the sphincters act naturally throughout the whole course of the disease. The knee-jerk gradually disappears, as in other atrophic forms of paralysis. Fibrillary tremors, such as are seen in progressive muscular atrophy, are not generally to be noticed; but they have been observed in a few instances. The cutaneous sensibility is unimpaired. The legs and feet are often cold and damp and bluish. The heels are usually drawn up to a greater or less extent, by contraction of the *tendo Achillis;* and there may be a well-marked club-foot. Sometimes the knees are rigidly flexed. The intelligence may be perfect; but it is often defective, and in some of the cases recorded the patients have been idiots.

When the disease has developed itself to a certain point, it is described by Duchenne as remaining stationary for two or three years, or even longer. But at length a further advance takes place. If the legs only were affected, the arms are now involved. The muscles, however, which now lose their functions, do not show even an apparent hypertrophy, but are always reduced in size, although the histological change is exactly the same as in those which were earlier affected. Even those muscles which were at first enlarged ultimately shrink, until they too are obviously atrophied. The patient, who has generally now reached adolescence, becomes altogether unable to stand, or even to sit up; he is a prisoner upon his couch. Ultimately he dies of exhaustion, or is carried off by phthisis, or some other intercurrent complaint. Friedreich, however, remarks that a large majority of the cases hitherto recorded have been lost sight of, so that it is not known how they ended.

Ætiology.—Nothing is known as to the cause of pseudo-hypertrophic paralysis. As occasional exciting causes are mentioned unhealthy conditions of life, chills, over-exertion of the muscles, and the occurrence of convulsions or of an exanthem such as measles.

It often appears in succession in two, or three, or even four children of the same family, especially in the boys, and at the same age in all of them. As might be expected, the parents themselves have always been free from it; but its hereditary origin has often been traceable by its having occurred in brothers or other relations of the father or mother. Transmission is almost always through mothers to sons.*

Boys are far more subject to this malady than girls, the proportion, among seventy-seven cases collected by Friedreich, being sixty-four to thirteen. Of Duchenne's original fifteen cases only two were girls; of forty-one collected by Webber of Boston and quoted by Ross, only five; of thirty-three by Gowers, ten. In a remarkable series of cases recorded by Lutz it appeared in two successive generations in the female line only, affecting five girls. More often it attacks several sons of the same parents, and spares all the daughters.

Out of 75 cases in which the date of its commencement was ascertained, Friedreich found 45 in which it began under five years of age, 17 between six and ten, 8 between eleven and sixteen. In the remaining 5 cases the patients were adults; and 2 of them were aged forty and forty-one respectively when the disease began. There was in 1887 a patient in Guy's Hospital under Dr Frederick Taylor, a youth of eighteen, in whom this disease had developed within only a few months.

Dr Port, of the German Hospital, showed two cases at the Hunterian Society (1887–8), in brothers aged fourteen and nine years. Their four sisters were healthy and one brother; but three other brothers had died after showing symptoms of the same disease.

In eight cases at Guy's Hospital six were in male and two in female patients; two were under ten, and four between ten and twenty.

Diagnosis.—This is very easy in well-marked cases. One morbid state, which must be thought of in connection with it, is that which Brodie and Hilton both believed to depend on the hip-joints being congenitally placed too far backwards; the drawings given in Hilton's work show a compensatory curvature of the spine very like that which is seen in pseudo-hypertrophic paralysis, so that one is inclined to wonder whether his cases could possibly, after all, have been examples of that disease in a slight form. Dr Leech's "harpoon" enables one to examine the muscular tissue during life, and is said to be more useful than Duchenne's *emporte-pièce*. That enlargement of the muscles is not always a conspicuous symptom is certain; unless it should prove that Duchenne and Friedreich were wrong in including under the present head the cases described by Dr Meryon in 1852 under the name of "granular and fatty degeneration of the voluntary muscles," which occurred at about the same age in several boys belonging to two families. Meryon found a different morbid change in the muscles; but it must be remembered that his investigations were made after death had occurred at a very advanced period of the disease, and not upon portions of muscle removed during life. Charcot and Sir William Roberts, however, regard the cases in question as examples of progressive muscular atrophy; and it is to be noted that Friedreich himself relates as instances of the latter disease several cases

* In this character of chiefly affecting males but being chiefly transmitted through females, this curious disease resembles Hæmophilia.

which seem to belong to the same class as Meryon's (cf. p. 514). They occurred in three families residing in or near Heidelberg; and what is very curious is that Hemptenbacher, a pupil of Friedreich's, succeeded in tracing all three families to a single pair of ancestors a century and a half back. A similar malady is said by Eichhorst to have appeared in six successive generations in a family at Königsberg.

Pathology.—Charcot and most other writers at the present time hold that this disease is primarily an affection of the muscles themselves, and thus differs absolutely from progressive muscular atrophy, which has been traced to a lesion in the grey matter of the cord. But we have seen that in progressive muscular atrophy, and even in the atrophic paralysis of children, the wasted muscles often have their bulk made up to the natural standard by an interstitial development of adipose and fibrous tissues, so that if, on the other hand, an apparent overgrowth of the muscles is not an essential feature of pseudo-hypertrophic paralysis, one cannot help suspecting that it must, after all, have close relation to the other atrophic diseases. Indeed, although Pierret and Charcot studied with great care the histology of the cord in a fatal case of M. Bergeron's, and detected no morbid change in it, afterwards Lockhart Clarke and Gowers recorded a case in which they discovered extensive areas of disintegration in various parts, in some of which the nerve-cells were in a state of atrophy. Dr Fagge was strongly inclined to the opinion that pseudo-hypertrophic paralysis will ultimately be found to be a spinal affection, and since the first edition of this work was published Dr Ross and Dr Bramwell have each found changes in the spinal cord. The former observer, however, has in a second case found the cord and nerves of the paralysed muscles unaffected, and the lesions recorded by the latter were either congenital or secondary and recent. Accordingly Dr Ross has, in the second edition of his treatise, abandoned the theory of a spinal origin, and come to the conclusion that pseudo-hypertrophic paralysis is a primary and idiopathic atrophy of the muscles. Dr Gowers also holds that "the essential lesion is the growth of connective tissue by which the muscular fibres are damaged, whether fatty tissue is found or not."

The nearest allies of this curious disease are the hereditary juvenile and probably myopathic forms of progressive muscular atrophy last described.*

Treatment.—There is unfortunately very little to be said on this point. Duchenne believed that he cured two cases (the details of which are given in the 'Archives Générales' for 1868) by faradisation of the affected muscles, with the aid of hydrotherapeutics and massage; they were both in an early stage, with but slight enlargement of the gastrocnemii. At a later period of the disease he found treatment of no use. Benedikt has recorded three cases in which he obtained results by "galvanising the sympathetic," but in the hands of Erb this procedure has since signally failed. Meryon believed that the administration of arsenic retarded the progress of his cases. When contractures have occurred, so as to produce talipes, division of the tendo Achillis has sometimes been useful, by enabling the patient to walk until the muscular atrophy has advanced to a further stage.

* Is it not possible that the apparently inconstant changes in the cord may be the result and not the cause of the muscular atrophy, like the atrophy of motor nerve-cells found by Dr Dickinson and other observers as the result of amputation? ('Journ. of Anat.,' 1869, p. 88; see also Dr Dreschfield's case, *ibid.* 1879, p. 424, and Mr. Bowlby's 'Injuries and Diseases of Nerves,' p. 27, with reference to Vulpian's experimental results.)

Primary multiple muscular atrophy is a condition closely allied to the preceding, but differing in the fact that there is no stage of apparent hypertrophy. Cases will be found mentioned in Dr Poore's edition of Duchenne's great work, and in Dr Gowers' treatise. They occur in families, and sometimes reappear for several generations. Thus Barsickow, in a thesis on the subject, quoted by Gowers, found twenty-four cases in five generations. The affection is not much, if at all, more frequent in men than in women, and usually appears, not in childhood, but in early adult life. It often begins in the muscles of the face, giving what has been called the "myopathic expression," or rather want of expression. When fully developed the condition is much like that of advanced progressive muscular atrophy, and probably some of the cases might take their place as examples of Duchenne's "juvenile" type referred to above (pp. 513, 514).

ATROPHIC PARALYSIS FROM LEAD.*—The most common effect of chronic poisoning by lead upon the nervous system is a peculiar form of paralysis affecting the upper limbs, and known as "the dropped wrist."

This attacks certain groups of muscles much more often than others. Generally the extensors of the hand are the chief ones to suffer; the patient's hand hangs powerless from his wrist, and his fingers are more or less forcibly flexed. When the forearm is laid prone upon a table he is unable to turn it round so as to bring the palm uppermost, but the supinator longus generally escapes. The muscles which form the ball of the thumb are affected very frequently and sometimes before any others; also those of the little finger, the lumbricales and the interossei. In some cases the deltoid muscles are first attacked, and with them the lower part of the trapezii† and the muscles which cover the dorsal surface of the scapulæ. The affected muscles always become atrophied. Thus the ball of the thumb, instead of being rounded, is sunken; the loss of substance in the lumbricales causes the flexor tendons to be visible in the palm of the hand; the neighbourhood of the external condyle of the humerus and the back of the forearm are hollowed out and flaccid. If the shoulder is attacked, it loses its roundness, and the outlines of the bones can be felt much more plainly than is natural. In some cases the whole upper limb may be weak and all its muscles more or less wasted. But the biceps and triceps in the arm and the flexor muscles in the forearm are never so much affected as the extensors.

Most frequently both upper limbs are attacked, but one much more than the other. Sometimes the paralysis is limited to one arm and hand. Perhaps the difference is due to the fact that one arm has been used more than the other in the patient's daily work.

The paralysis which occurs in chronic plumbism is not always confined to the upper limbs. In the legs the peronei are first attacked. In two instances at Guy's Hospital the whole body was affected. The patient could not walk nor raise himself in bed.

* *Syn.* Saturnine palsy.—This term and the corresponding one of Saturnine gout are survivals of the astrological chemistry which connected the seven principal metals with the "seven stars"—gold with the sun, silver with the moon (witness "lunar-caustic"), iron with Mars, quicksilver with "Mercury," tin with Jupiter, copper with Venus (*diva potens Cypri*), and lead with Saturn.

† This curious immunity of the upper part of the trapezius also obtains in progressive muscular atrophy. Compare the muscles most often affected in that disease (p. 497), and in infantile palsy (p. 491).

Pathology.—It was long a question whether lead paralysis is due to an affection of the nervous centres in the cord, or to the local action of lead circulating in the blood upon the muscles themselves. John Hunter long ago took advantage of a fatal accident which had happened to a painter to examine the tissues of his paralysed hand and arm, and he found that the muscles were cream-coloured. Some years ago a man died in Guy's Hospital who had been attacked with lead paralysis seven years before, and had never completely recovered from it. Dr Moxon found that the affected muscles—especially the deep extensors of the forearm—were represented only by loose watery connective tissue.

The tenderness of the muscles, and the marked electrical reaction of degeneration shown by the paralysed muscles, make it probable that lead palsy is due to peripheral neuritis (perhaps affecting the anterior roots of the nerves) rather than to disease of the cord, or to primary atrophy of the muscles.

Diagnosis.—We have already seen the close relation between the symptoms of lead-palsy and those of chronic atrophic spinal paralysis (p. 496). The only other disease for which saturnine paralysis is likely to be mistaken is progressive muscular atrophy. One distinction between them—on which Sir William Gull used to lay stress—is that in chronic plumbism the patient complains of pain when one grasps the affected muscles with one's hand. Moreover, it is not attended with the fibrillary tremors which accompany progressive muscular atrophy. But the most remarkable distinction is afforded by the application of galvanism to the skin over the affected muscles. In lead paralysis faradism causes but slight contraction or none at all, whereas interrupted galvanism gives rise to movements more readily than in health, that is, a smaller number of cells is required to excite the muscles to contract, and the other peculiarities of the reaction of degeneration are well marked. This is absent or ill-developed in progressive muscular atrophy.

The exemption of the supinator longus is so constant as to be often of help in diagnosis. The gums must be examined for the *blue line* which is practically pathognomonic; its peculiar characters will be described in the chapter on Lead-colic. One must ask whether the patient has suffered from pain in the abdomen with constipation; but it is to be borne in mind that when a person has been slowly absorbing the metal in minute quantities for a long time, paralysis often occurs without having been preceded by any pain in the bowels, and these are precisely the cases which are difficult of diagnosis. Sometimes the recognition of chronic plumbism is materially facilitated by the peculiarly sallow and anæmic aspect of the patient.

Another nervous affection which is said to be an occasional result of lead-poisoning is a *tremor*, resembling that caused by mercury. It has hitherto only been observed, by Brockmann, among the miners on the Harts. It is generally limited to the arms and hands, but it very often attacks also the lips and the angles of the mouth. Very rarely it attacks the legs and the muscles of the head and of the trunk.

Treatment.—The medicine most useful in lead palsy is iodide of potassium. Dr Anstie lays stress on the importance of a nutritious diet, and on the value of cod-liver oil in such cases. Sulphur baths have been supposed to be serviceable. They lead to the excretion of some of the lead which has been accumulated in the body; a blackish discoloration of the skin, and still more of the nails, is observed which does not at once rub off, and which evidently is due to the conversion of some of the lead present on the body into a sulphide.

Locally the application of a continuous current, just sufficiently powerful to excite contraction of the affected muscles, is very useful. As soon as they will react to faradism, that form of stimulation may be substituted.

Other effects of plumbic intoxication will be referred to under the headings of Epilepsy and Insanity, Lead-colic, Chronic Interstitial Nephritis, Saturnine Gout, and Anæmia. It is also a cause of abortion and myalgia.

It will be convenient here to refer briefly to the effect of other metallic poisons on the nervous system.

MERCURIAL TREMOR.*—This disorder, once common among looking-glass makers and other workers in quicksilver, has now happily become very rare.

The first thing which a man notices when he is beginning to suffer from mercurial tremor is that he is no longer sure of his arms and hands. So soon as he attempts to take hold of anything they shake. After a time every effort leads to jerking movements. When his arm is bent it is not by a continuous motion, but by fits and starts. His hand cannot be directed with precision to any object, but is thrown to one or the other side of it; when he has even grasped a thing he is often unable to let it go. Presently the lower limbs are affected; he may have to be led, and when he walks his limbs may tremble and dance about, so that (as Sir Thomas Watson says) they look as if hung upon wires. His tongue may become tremulous, his speech may be hurried, jerking (or *staccato*), and at length unintelligible; this last symptom constitutes what has been termed *psellismus mercurialis*. When the tremor has once been excited by exertion or emotion the man himself is unable for a time to stop it, but if he remains quiet for a little while it passes off, and does not return until he has to make some fresh effort. Getting some other person to grasp the affected limbs sometimes controls their movements.

The commencement of mercurial tremor is generally gradual, but sometimes it is sudden, and a fit of passion has seemed to act as an immediate exciting cause of it. It is said to be more apt to occur in the cold and damp weather of winter than at other seasons.

As might be expected, salivation often accompanies the more severe forms of mercurial tremor. The teeth become loose, the gums are ulcerated, the breath is fœtid. The patient grows weak, anæmic, and thin. His teeth are said to become black, and his skin has been described as acquiring a remarkable brown hue. After a time he may begin to suffer from headache and loss of memory, he may become delirious, and at length comatose, and in this way the disease may terminate fatally.

The disease, in fact, tends to advance so long as the patient remains exposed to the influence of the poison, but when he is withdrawn from it the tremor commonly subsides in two or three months. Sometimes, however, the recovery is incomplete, the upper limbs being those which are most apt to remain unsteady. Relapses are frequent, and each successive attack is commonly more severe than the previous ones.

* *Syn.*—Mercurial Shaking Palsy—The "trembles"—*Fr.* Tremblement des Doreurs (Mérat), 1812—*Germ.* Mercurialzittern.

The following is De Haen's account of the disease in one of the miners of Idria more than a century ago, as cited by the late Dr Sanders, of Edinburgh:—"Deaurator, quinque et viginti annorum, horrendo artuum omnium maxime superiorum vexatus, ita ut nec comedere, bibereve solus, neque loquens amplius intelligere potuerit. Nutriendus, vestiendus, et (infantis instar) alvum urinamque positurus, adjuvandus erat: dolorum cæterum immunis."

The workers in quicksilver mines—in which the ore is exposed to heat—are said to suffer severely from mercurial tremor. Formerly it was common enough in this country among "water-gilders," who employ for gilding an amalgam of mercury and gold, from which the volatile metal is expelled by the action of a charcoal fire. But water-gilding is now almost superseded by electro-plating. Another occupation in which mercury is used extensively is that of "silvering" mirrors; this, however, comparatively seldom gives rise to the tremor, probably because the quantity of metal volatilised is but small, since heat is not employed. But mercury does give off vapour to some extent, even at 68° or 70°, so that it is not impossible for the disease to show itself in those who have to deal with the metal at ordinary temperatures. In 1864 a man, suffering from an extreme form of mercurial tremor, was admitted into Guy's Hospital under Dr Rees. He had merely been engaged in packing up skins which had been previously washed with an acid solution of mercury. He said that he had at one time been salivated, but some doubt would perhaps have remained as to the cause of his symptoms, which terminated fatally, had not Dr Swayne Taylor succeeded in obtaining mercury from the kidneys, and (in smaller quantities) from the brain and liver ('Guy's Hospital Reports,' Third Series, vol. x, p. 176). This man had worked at his occupation for three years before he began to suffer to any considerable extent. It is generally said that a time varying from two to twenty-five years is required for the production of mercurial tremor. Sir Thomas Watson relates the case of a man who had been a water-gilder for seventeen years before he was attacked.

There is reason to believe that the disease is sometimes due, not to the inhalation of mercury, but to its absorption by the skin. Dr Mapother states that the anatomy porter of the Irish College of Surgeons, who at one time rubbed enormous quantities of mercury into the bodies of persons affected with syphilis, was for thirty years subject to mercurial stammering. Even the internal administration of this remedy has been known to cause tremor in those who have taken it for a very long time.

The *diagnosis* of mercurial tremor is very easy, except in cases such as that which proved fatal in 1864 in Guy's Hospital, in which the patient might be unaware that he was exposed to the action of the metal. In its earlier stages it is liable to be mistaken for paralysis agitans; in its later periods for chorea. Anstie ('Lancet,' 1872, i, p. 734) mentions the case of a man who was supposed to have died of delirium tremens, until it was afterwards discovered that in his trade he had been inhaling the fumes of the acid nitrate of mercury.

Treatment.—Much has been done to prevent the occurrence of this disease in those whose occupations would otherwise expose them to it. The workshops are freely ventilated and provided with flues or chimneys. In some places it has been found practicable to interpose a glass screen between the upper part of the workman's body and the fire by which the mercurial vapour is set free. Personal cleanliness, frequent ablutions, and avoiding to take food in the room where the work is carried on, are regarded as very important, and it is said that abstemiousness in the use of alcoholic stimulants exerts a beneficial influence, though there may be a doubt whether the effects of intemperance have been isolated from those of other careless habits, which would be apt to prevail in conjunction with it.

Like other forms of tremor, that which is caused by mercury is often diminished for the time by a glass of wine or of some other stimulant. Sir

Thomas Watson's patient said that when the disease was first coming on he found himself unable to get upstairs to his work until he had taken half a quartern of gin.

Among medicines iodide of potassium appears to be the most useful. It was suggested by Melsens on the same theory as for chronic lead-poisoning, and mercury has been said to have been detected in the urine while it was being taken. Sudorific remedies have been recommended, but Sir Thomas Watson says that he found tonics, and particularly iron, more useful than any other drugs in the case which he relates. Anstie found cod-liver oil very useful in several cases. Sir William Gull some years ago recorded an instance in which electricity appeared to be beneficial, sparks being taken from the spine. It was thus also that De Haen's patient (whose case was quoted above in a note) was cured.

BRASS-FOUNDERS' AGUE.—*Tremors from zinc-poisoning.*—There is a curious disorder to which brass-founders are liable; it was studied by Dr Greenhow in Birmingham, in 1858, and named by him "brass-founders' ague," on account of the resemblance between its symptoms and those of a paroxysm of intermittent fever ('Med.-Chir. Trans.,' vol. xlv). It is in no way dependent upon malaria, but is caused by the dense white fumes of oxide of zinc, the result of deflagration of the metal, which, at a certain stage in the formation of brass, fill the casting-shop, unless it is very well ventilated. Exposure to these fumes is followed by malaise and weariness, by a sense of constriction at the chest, and sometimes by nausea. Afterwards shivering comes on, with chattering of the teeth; this is succeeded by a more or less marked hot stage, and the attack ends in very profuse sweating. Next day the man feels out of sorts, but not enough to be unable to work. There is no regularity in the recurrence of the attacks, which come on from time to time under the operation of their exciting cause, but especially when the patient has been off work for a few days. They seem not to impair the health, and it is not known that they shorten the life of the patient. Drinking milk is said to be preventive of the brass-founders' disease.

Dr Greenhow reported that, beside this effect, brass-workers at Birmingham are very liable to shaking palsy. He could only find, however, one case in an old man. Dr Gee has lately published in the 'St Barth. Hosp. Rep.' for 1889, p. 28, a case of a brass-founder, aged thirty-three, who suffered from muscular paresis, trembling tongue, and ankle-clonus, which symptoms were ascribed to zinc-poisoning. See also a good account of the so-called "ague," the bronchitis (coniosis), and the nervous symptoms to which the Birmingham brass-founders are liable, by Dr Robert M. Simon ('Brit. Med. Journ.,' April 28th, 1888). He is inclined, with Dr Hogben, to attribute part of the poisonous effects to the copper, rather than the zinc of the compound metal.

Arsenic is an occasional cause of paralysis, affecting the lower extremities more frequently than the arms. This, like lead-palsy, is believed to depend on peripheral neuritis.

TABES*

'Η νωτιὰς φθίσις ἀπὸ τοῦ μυελοῦ γίνεται
HIPPOCRATES: de morbis, lib. ii, cap. 19.

Histology and nomenclature—Ataxic symptoms—Anæsthesia—Paraplegic symptoms—Lightning-pains—Visceral pains—Loss of knee-jerk—Disorders of the eyes—Atrophy of joints—Perforating ulcer—Other complications—Course and event—Anatomical seat and histology of tabes—Relation between the ataxy, dysæsthesia, and other symptoms—Ætiology—Diagnosis—Prognosis and treatment.

Hereditary tabes: Friedreich's disease, its symptoms and pathology.

History and nomenclature.—Among the chronic affections of the spinal cord there is one which is characterised by an impairment of the power of co-ordinating or combining the actions of muscles in the execution of movements. That it is not an ordinary paralysis is evident from the fact that in some cases the contractile force of the muscles is undiminished. It was carefully described by Duchenne, of Boulogne, in 1858, and he named it *ataxie locomotrice progressive.* But there is no doubt that Romberg had described under the title *tabes dorsalis* most of the principal symptoms of ataxy in 1851, before Duchenne wrote on the subject; and the French observer seems to have somewhat underrated the value of the work of those who had preceded him, although it is incorrect to say that he altogether ignored it.

A series of cases was described by Gull in 1856–7. But earlier still Todd, in 1847 ('Cyclop. of Anat. and Phys.,' iii, p. 721), pointed out the distinction between paralysis and loss of the power of co-ordinating movements, and mentioned the difficulty of walking and the tottering uncertain gait which result from ataxia, while considerable voluntary power may remain. He did not name the latter affection, but his knowledge went beyond that of Romberg and Duchenne in assigning its seat to the posterior columns of the cord.

We now know that though locomotor ataxia is a frequent, it is not the earliest, and not even a constant, symptom of this remarkable disease; so that *tabes* is a far better word. The adjective dorsalis or spinalis is seldom needed, for *tabes mesenterica* is a term now seldom used.†

* *Synonyms.*—Tabes dorsalis *v.* dorsualis—Spinal tabes—Locomotor ataxia—Ataxie locomotrice progressive (Duchenne)—Asynergie locomotrice (Trousseau)—Posterior spinal sclerosis—Chronic posterior leucomyelitis.—*Fr.* Ataxie locomotrice—*Germ.* Tabes dorsalis, Hinterstrangsclerose.

† The original meaning of Tabes dorsalis was purely clinical, and had reference to the weakness and pains in the back, the malnutrition and other disorders which follow excessive sexual indulgence. In fact it nearly answered to what is now called Neurasthenia spinalis. *Tabes dorsalis* from this cause is regarded by Cullen in his nosology as a species of atrophy, distinguished from that of phthisis, of mesenteric tabes, and of chronic suppuration, only by the absence of fever. Celsus has no dorsal variety of Tabes.

Now, however, the word *tabes* is not used, any more than its Greek equivalent *phthisis*, to denote generally wasting, atrophy, or marasmus. "Tabes mesenterica," is tubercular enteritis and peritonitis, with swelling (probably always secondary) of the mesenteric lymph-glands. It is so different from Tabes dorsalis in its clinical features and associations, that confusion can scarcely arise. There is therefore no reason against the term

Clinical characters.—The onset of tabes is always insidious and its progress gradual. Ataxic symptoms may only appear after months or years marked by pains, by loss of knee-jerk, or by contracted pupils. Nevertheless they are the most constant and characteristic, and may properly be first considered.

Motor symptoms.—Ataxia begins almost invariably in the lower limbs. In walking the patient lifts his foot high in the air and throws it outwards, and then he brings the heel to the ground with a stamp. If the case is a slight one, it is at first only in starting that he experiences a difficulty. Wilks relates how a gentleman whom he knew, if he stopped to look in at a shop-window, had to ask someone near to give him a push before he could set off again. Once fairly started, he did pretty well, but found himself unable to turn sharply round without stumbling. Another patient, when he had once walked some distance along a road, wanted to go back, but could only do so by guiding himself up against a bank, when he fell down. A third, an out-patient, one day apologised for being late at the hospital by saying that his friends had sent him off in a wrong direction, and that he went on until he fortunately met an acquaintance who turned him round.

Some writers describe ataxic patients as rolling and staggering like persons who are intoxicated, but Wilks says that the gait rather resembles that of a man walking on a ledge who is anxiously balancing himself. The distinction is a real one, but many persons in the early stage of the disease have been condemned by their neighbours as drunkards. The attempt to run, or to hop, or even to ascend stairs, makes the patient's incapacity still more manifest, he is unable to stand on one foot, or with the two feet close together, without tottering or falling. If told to walk in a straight line—as along one particular board in a floor—his course is sinuous and irregular. The use of a stick, or leaning upon the arm of a friend, has an extraordinary effect in steadying his movements. In more advanced cases, however, as soon as he attempts to stand, his legs are violently jerked in all directions, and this, even though he may be held up on each side by an attendant. When lying on a couch he cannot carry the foot straight towards an object so as to touch it, nor raise the leg up in the air with an even movement. Yet he can exert considerable power in moving his legs against pressure, as in lifting a weight upon his knees.

The disorder may last for years without extending beyond the lower limbs, but in many cases it sooner or later affects the arms. The patient then becomes incapacitated for actions requiring delicate manipulation, such as writing or playing the piano; he cannot fasten his necktie or button his clothes. If he is told to bring the two forefingers into contact from a distance, they miss one another repeatedly. He cannot touch his own nose or rub his own eyes with certainty. He finds a difficulty in taking hold of anything held up before him, and when he attempts to draw or write in the air with his finger, the fingers are moved zigzag in all directions.

Sensory symptoms.—Feeling is more or less impaired in cases of tabes. Subjective feelings of numbness, or of formication, are very often complained of. The patient says that when he stands his feet seem to be covered with thick woollen stockings, or to be treading upon a water-bed, or upon india-

Tabes (or, when needful for distinction from Tabes mesenterica, Tabes dorsalis) being used. It has every character of a good name. It is short, classical, unmeaning, distinctive, and capable of forming an adjective. This adjective is ready made: *tabidus*—not *tabeticus*.

rubber. The cutaneous sensibility may be found diminished in the feet, the legs, or even the thighs, when carefully tested as described at p. 403; but there is rarely any approach to complete anæsthesia. Ability to feel pain is often absent (*analgesia*), while tactile impressions are readily perceived, and patients generally retain the power of appreciating differences of temperature long after they have lost common sensation. That curious symptom, the retarded transmission of impressions, is almost peculiar to locomotor ataxy. It especially concerns the sense of pain, but Hertzberg believed that tactile impressions and those of heat and cold may also be delayed. If there is no anæsthesia, the prick of a needle may first be only felt as a touch, and then, after an interval, a sensation of pain may follow. Erb says that the interval may be one of some minutes; Cruveilhier, who seems to have been the first to draw attention to the symptom in question, noted it at twenty or thirty seconds. Another point is that the pain produced by a slight injury may last longer than under normal circumstances and gradually culminate, and, as a consequence, that the patient becomes unable to count a series of similar impressions if they succeed one another at all quickly.

These paræsthesiæ are by no means limited to the lower limbs. Sensations of numbness are often felt in the parts of the hands supplied by the ulnar nerves, even at the commencement of the disease. Trousseau found in some cases that the mucous membrane of the mouth is anæsthetic, the patient not being able to feel the food between his lips, nor to appreciate its temperature.

A symptom on which French writers lay great stress, as indicative of locomotor ataxy, is the failure to execute movements as well with the eyes shut as when they are open; and there is no doubt that this symptom is often marked. Many a patient who can stand quite steadily so long as he is looking down at his feet totters, and falls when he is made to close his eyes. It may be the first indication that anything is amiss; thus, in a case recorded by the late Dr Bazire, a man believed himself to be quite well until he noticed that he could not wash his face in the morning unless he could lean against a wall; for as soon as he shut his eyes, he lost his balance and staggered.*

Erb has found that this symptom of inability to execute movements accurately with the eyes closed is wanting in certain cases of tabes, those, namely, in which sensation is absolutely unimpaired. On the other hand, it is invariably present when there is much anæsthesia. He admits, indeed, that it may often be noticed in cases in which there is no loss of sensation in the skin; but he supposes that there is failure of the so-called muscular sense. A patient suffering from any spinal disease may be expected to totter in attempting to stand with his eyes shut, if he has imperfect sensation in his legs and feet, although the want of stability is exaggerated and made more manifest by defect of co-ordinating power. Another view first put forth by Leyden is that the want of co-ordination or ataxy is itself the direct result

* According to Jaccoud, the effect of keeping the eyes open is in part due to the influence of light; for he says that a person who has ataxy cannot walk so well when they are closed as when they are open, even when something is held in front of his chest so as to prevent his seeing his feet. But, as Dr Bazire has remarked, this is no doubt due to the feeling of confidence inspired by looking about one, for nervousness has a marked tendency to augment the symptoms of the disease: a patient who is conscious of being observed by others cannot walk nearly so well as when he supposes himself to be unnoticed. A similar explanation may apply to the fact noticed by Benedikt and Friedreich, that some ataxic patients who are blind totter more when they are made to shut their eyes.

of disturbance of tactile and muscular sense. In any case the test of walking with the eyes shut, though practically useful in the diagnosis of tabes from rheumatism, neuralgia, or other peripheral affections of the limbs, does not distinguish one lesion of the spinal cord from the rest.

Paraplegic symptoms.—In some cases of tabes the power of the muscles is undiminished. Duchenne invented the dynamometer for the purpose of demonstrating this fact. In the case of certain muscles, a rough estimate of their strength can easily be made. For example, one can measure that of the quadriceps extensor by getting an assistant to fix the lower part of the thigh, and then telling the patient to keep the knee straight, while one forcibly flexes it. Or one can test the force of the psoas and iliacus muscles by placing him in a chair and making him lift his knee, while at the same time one resists this movement by pressing with both hands upon the knee. Or, following Trousseau's plan, one may determine what weight the patient is able to bear upon his shoulders while standing with the support of a friend's arm or leaning against the wall. A young man under his care could support a hundred and sixty pounds in this way, and another patient carry on his back a doctor who had supposed him to be paraplegic. But, while the theoretical importance of these observations is very great, as showing that locomotor ataxy may be altogether independent of paralysis, it is a great mistake to suppose that all, or nearly all, of the patients who exhibit a want of muscular co-ordination have their muscular power undiminished. On the contrary, one often finds it much enfeebled, and some of the earliest symptoms in these cases are commonly inability to continue standing for long, and fatigue after walking a short distance. It is true that the suggestion has been made that such sensations are really muscular paræsthesia, and do not prove a loss of motor power; and Duchenne records their presence in the patients in whom he demonstrated that the force of the muscles was unimpaired. But our experience is in accordance with that of Erb, who found evident paresis in at least half the cases in which other characteristic symptoms of tabes existed.

Possibly loss of motor power may be due to a complication of posterior sclerosis, the special lesion of tabes, with chronic and more diffuse myelitis. This is confirmed by the not very infrequent existence of the paraplegic symptom described as "girdle-feeling." Trousseau speaks of some of his patients feeling as if the chest or the legs were compressed by an india-rubber cuirass or stocking. Or the sensation may be that of a belt round the waist, of a garter tied below the knee, or of a tight shoe on the foot.

Again, if we inquire how the functions of the *pelvic viscera* are carried on in ataxy, we shall find but little to distinguish tabes from the slighter forms of paraplegia. Thus the bladder is apt to be irritable, and its muscular power may to some extent be diminished, so that the urine no longer flows in a good stream, or is from time to time passed into the bed. Erb notes that the fæces are sometimes discharged without the patient's knowledge, and attributes this to a loss of sensibility in the mucous membrane of the sphincter. The sexual functions are almost always impaired. At an early stage the genital organs are often extremely irritable. It is said that this condition may be accompanied with an increased virile power, but much more frequently there is marked weakness. As the disease advances the patient generally becomes altogether impotent, although there seems no doubt that some persons have been able to beget children after having

symptoms of tabes for years. Bedsores do not appear, at least until the last stage of the disease.

One of the most constant of all symptoms of tabes, first pointed out by Westphal, is *loss of the knee-jerk*. This begins early, and probably continues unchanged throughout the disease. The true superficial reflexes are usually and progressively diminished in proportion to the anæsthesia, but are never absent as in atrophic paraplegia; they are sometimes greatly exaggerated in the early stages, as much so as in many cases of spastic paralysis. Of the visceral reflexes, that of the cremaster is usually impaired, along with loss of sexual power.

The *electrical reaction* of the muscles is often perfect, but sometimes slightly augmented or impaired. They remain well nourished until the disease has reached an advanced stage; but this is likewise the case in paraplegia, unless the anterior cornua of the lumbar cord are affected.

Ultimately many tabid patients pass into a condition of complete paraplegia with atrophy of the muscles, bedsores, paralysis of the bladder, and cystitis.

In exceptional cases of ataxy paraplegia is so marked a symptom that they must be described separately as Ataxic Paraplegia. In most cases this is of the spastic kind, and depends on lateral sclerosis complicating that of the posterior columns. Occasionally also we find atrophy of the muscles set in during cases of tabes, and conclude that the chronic interstitial inflammation has extended to the anterior cornua.*

Pains.—Tabes frequently is attended with certain remarkable early symptoms, warnings, or *prodroma*, which belong to no other spinal affection. Chief among these are sudden pains in the lower limbs or elsewhere. These may either be of a stabbing or boring character, as though a sharp instrument were thrust into the tissues at the spot, which is generally near a joint; or they may be like flashes of lightning or electric shocks shooting down along the course of a nerve. Charcot says that they are worse at night. They last but an instant and return again and again during a period of from four to eight days, after which they may disappear altogether for a fortnight, or even for some months. Their occurrence seems to be favoured by changes of weather. Erb remarks that he has often been struck by the unanimity with which different patients have complained of them on some particular day when there has been much wind, or a fall of snow or of rain. It is also said that they are especially liable to return at spring and autumn, and that they may be brought on by over-exertion of body, mental emotions, or the excitement of coitus. They are sometimes of the most agonising character, sometimes so slight that careful inquiries are needed to elicit the fact of their presence. They are often called "neuralgic" or "rheumatic." They frequently spread from the legs to the trunk, much more rarely to the arms. They may go on for five, ten, or fifteen years, before any other symptoms show themselves, and they often persist throughout the whole course of the disease. As to the frequency of their occurrence, Topinard found that they were wanting in only 22 cases out of 104, Erb in only 8 out of 60, Cyon that among 203 patients there were 138 in whom they were said to have been present, but no more than 8 in whom they were expressly stated to have been absent.

* Dr Gowers has described Westphal's "Ataxic Paraplegia," with lateral and posterior sclerosis, which he recognises in his 'Dis. of Nervous System,' vol. i, p. 341, as a separate affection; see also 'Lancet,' July 3rd, 1886.

Visceral pains.—Other early symptoms mentioned by Charcot are pain in the bladder or in the urethra, with a constant desire to micturate, and a sudden pain in the rectum. Certain strange attacks of pain in the stomach, *crises gastriques*, which were first noticed by Delamare in 1866, consist of lightning-like pains, which start from the groins and pass up both sides of the abdomen towards the shoulders. They are generally accompanied by palpitation of the heart and a quick pulse, by vomiting (of a liquid at first clear but afterwards stained by bile or blood), and by giddiness and malaise. They commonly last for two or three days at a time, and then pass off entirely. They must be carefully distinguished from the gastrodynia of dyspepsia, to which tabid patients are as liable as other people.

Ocular disorders.—Of the symptoms of tabes, which Charcot calls *cephalic*, affections of the ocular muscles, of the iris, and of the optic nerve are the most important.

The functions of one or other of the branches of the third nerve on one side, or of the sixth nerve, may sometimes be annulled, so as to cause diplopia, strabismus, ptosis, and various other disorders, such as have been described in a previous chapter (p. 413). Von Graefe is said to have remarked that in tabid patients, when they have double vision, there is little tendency to fusion of the images, and that this points to a central origin. The ocular paralysis may be transitory, or may last a few days, or may persist for weeks or months; it may return again and again; and may at last become permanent.

Another common symptom is inequality of the pupils, one of them being constantly smaller than the other. Still more frequently both irides are symmetrically contracted to an extreme degree; this *myosis* is often among the earliest warnings. Moreover, the pupils are insensible to the stimulus of light, but contract with accommodation for near objects; the recognition of this important and nearly constant symptom of tabes is due to Dr Argyll Robertson, of Edinburgh.

Impairment of vision is frequent. This is said to develop itself as a progressive narrowing of the visual field, generally from without inwards, until the only part of the retina that remains sensitive to light may be a small patch to the inner side of the blind spots. It is accompanied by achromatopsy; the perception of green being generally the first to disappear, then that of red, and lastly that of yellow and blue. The defects of vision are commonly worse in bright light, so that the patient sees better after sunset. The pupils are often permanently contracted when there is nearly complete blindness. The ophthalmoscope in many cases reveals atrophy of the disc, which in advanced stages is perfectly white, with sharply outlined edge, and very small arteries, whereas at an earlier period it may be greyish in colour. The two retinæ generally suffer together; the affection is a progressive one, and commonly goes on until there is complete amaurosis.

The frequency of these ocular symptoms is very considerable. Erb estimates that, if slight and transitory phenomena are reckoned up with the rest, paresis of the ocular *muscles* is present in more than half of all the cases of ataxy; and that it is persistent in one third or one fifth. How often the optic discs undergo atrophy cannot yet be stated accurately; ophthalmologists are apt to rate it too high, physicians too low; Erb observed it only 8 times in about 70 cases. Topinard found visual disturbances in 49 of 102 cases; and Cyon, amblyopia or amaurosis in 60 of 203

cases. Optic neuritis often occurs at a very early period; according to Charcot, it may precede all other symptoms of ataxy by ten years.

The contracted pupils and the peculiar reflex which is named after Dr A. Robertson are the most frequent of all cephalic symptoms.

Arthropathy.—Another most curious occasional complication of tabes—and often a very early one—is an *affection of the joints*, which has been specially studied by Charcot. Its most common seat is the knee, next in frequency comes the shoulder, and then the elbow, the hip, the wrist. It is not traceable to any blow or other injury. It sets in suddenly with extreme swelling, due not only to effusion into the synovial cavity, but also to infiltration of the parts around. Yet there is generally neither pain, nor heat, nor redness. In the course of a few months the swelling may disappear, but more often the process goes on to destruction of the articular cartilages, with erosion of the ends of the bones and partial dislocation. Charcot says that it never occurs at an advanced period of the disease, except in the upper limbs, when they are beginning to be affected in their turn. This remarkable morbid process will be again considered along with Osteo-arthritis, to which it bears some resemblance.

Other trophic lesions occasionally seen in the course of tabes are: pigmentation or leucodermia in the course of the nerves, like the effects observed in ordinary neuralgia; herpetic eruptions like those of zona; painless ulceration about the fingers and toes which makes the nails fall out; painless loss of teeth, of which we lately had a striking case in Philip Ward; and, most remarkable of all, ulceration of the sole of the foot, which, still without notable pain, gradually bores deeper and deeper until it makes a sinus through to the dorsum. This *perforating ulcer of the foot* has been long known to surgeons, and is now believed to be most frequently a symptom of tabes.

Complications.—These are early and complete loss of motor power causing ataxic paraplegia, described by some authors as a separate disease; secondly, muscular atrophy, either from invasion of the anterior cornua, or according to Déjerine from peripheral neuritis; thirdly, cerebral symptoms, such as epileptiform fits, and occasionally hemiplegic attacks; and fourthly, general paralysis with insanity. Certain tabid symptoms, particularly loss of knee-jerk, are exceedingly common in asylums, often without locomotor ataxia. Cystitis, with other pelvic symptoms succeeding the slight affection of the vesical reflex, and optic neuritis with blindness succeeding the ordinary amblyopia, may be rather regarded as ingravescence of normal symptoms than as new complications.

Course and event.—Tabes is most insidious in its origin, most irregular, slow, and uncertain in its progress, and most intractable in its course. This is one of the greatest difficulties in tracing its natural history. Patients must be watched, not for a few weeks, but for months and years. They are common in our great hospitals, and by their frequent reappearance in fresh places, and under fresh observers, they give an exaggerated impression of their numbers; but autopsies on cases of tabes are rare.

After lightning-pains, loss of knee-jerk, and myosis have lasted for several years, there may still be no ataxic symptoms. After marked locomotor ataxia is developed, there may be long delay before the advent of the paraplegic, pelvic, or cerebral symptoms which belong to the latest stage. And after apparently steady, and, by comparison, rapid progress, the disease

may suddenly be checked and remain stationary for months or years. Still, the natural tendency is to ingravescence.

Anatomy.—Todd's statement, that in cases of lack of co-ordination without paralysis the lesion is situated in the posterior columns of the cord, has been remarkably confirmed by modern methods of investigation. The lesion is sclerosis (chronic interstitial myelitis, or grey induration with atrophy) of the posterior columns of Burdach. This change is first visible as a grey streak in the deeper part of the white wedge-shaped area presented by these columns (*fasciculi cuneati*) in transverse sections. It is most marked in the upper lumbar and dorsal regions, and diminishes in extent, both above and below. Sometimes it reaches upwards as high as the restiform bodies. Its histological characters are those which have already been given of sclerosis generally. In the more advanced stages most of the nerve-fibres have disappeared, their axis-cylinders being no longer discoverable; but even in the oldest cases a not inconsiderable number of them are found with their structure unaltered, scattered through the dense connective tissue, and can be readily recognised either negatively by carmine staining, or positively by help of osmic acid. The morbid process extends over the whole of the column laterally, including the root-zones and the posterior roots themselves, which become thin, grey, and atrophic. It also reaches the surface, and the pia mater is generally found opaque, thickened, and more or less adherent to the other membranes. The posterior cornua may be also found atrophied in advanced cases; and the sclerotic change is sometimes found to have spread to the posterior median columns (of Goll) or to the lateral columns; these, however, are probably, clinically as well as pathologically, mixed cases.

Romberg described as follows the posterior sclerosis in a typical case which was seen by himself and by Froriep:—"I was not a little surprised to find that the atrophy of the spinal cord (which, compared with the fresh cord of a man of the same age, fifty-two, was only two thirds of its size) was confined to the lower part of the posterior columns and the corresponding nerves. The medullary tissue (*i. e.* white substance) of the former had almost entirely disappeared, so that they were translucent and of a greyish-yellow colour. The posterior roots of the nerves were deprived of the nervous substance (*i. e.* myelin), and presented a watery appearance." He states that the lumbar and lower dorsal regions were alone affected, and that the anterior columns and nerve-roots were free.*

There have been many speculations as to the mode of origin of this lesion. Do the nerve-fibres first undergo degeneration, and is the growth of connective tissue secondary? Or is the original process chronic inflammation of the neuroglia, leading afterwards to atrophy of the nerve-fibres, as cirrhosis of the liver leads to destruction of its secreting cells? May the disease begin as a meningitis, and spread to the cord? or is its starting-point in the sensory nerve-roots? But the most important question is, whether the lesion itself is constant.

Trousseau refers to a case of twelve years' duration, which had been seen by Duchenne and accepted as typical; but when Gubler and Luys and Duchenne himself examined the cord and its posterior roots, they could

* We have already seen that Todd distinguished the symptoms of Locomotor Ataxy from Paraplegia, and on physiological grounds placed the disease in the posterior column of the cord. His hypothesis was confirmed in the cases he examined *post mortem* (1847). Mr Stanley, of St Bartholomew's Hospital, had described the same anatomical condition in a case of tabes (probably for the first time) in the 'Med.-Chir. Trans.' for 1840.

detect no alteration there, whereas many of the nerve-fibres had disappeared from the anterior roots. Dr Alex. Hughes Bennett published in the 'Clinical Transactions,' vol. xviii, a case which presented the classical symptoms of tabes during life; but the posterior columns were found healthy. The lesion was sarcoma of the bulb and recent cerebral disease, but the posterior nerve-roots were involved. He quotes two similar cases of "peripheral tabes" from M. Déjerine. The importance of such negative evidence is enhanced by the fact that the course of the disease is commonly so protracted as to give few chances of tracing it to its end in ordinary hospital practice.

It was at one time believed that sclerosis of the posterior columns may occur as the secondary result of local myelitis without any symptoms of tabes having been present during life. In cases of Pott's disease of the dorsal vertebræ, for example, ascending degeneration is often found in the posterior columns of the cervical part of the cord; but the co-ordination of the movements of the arms and hands is in no way affected. Pierret, however, observed that the secondary ascending sclerosis just described is limited to the internal fasciculi of the posterior columns, the columns of Goll. He finds that in cases of tabes these parts of the cord are affected in the cervical region, whether the upper limbs have escaped or were secondarily involved. But sclerosis in the external fasciculi of the cervical posterior columns (the *bandelettes externes*, or *fasciculi cuneati*, Burdach's columns) occurs only when there have been ataxia of the hands and arms, and other symptoms of tabes. The conclusion is obvious that sclerosis of the tracts of Goll is a secondary ascending degeneration, and has nothing to do with the symptoms of tabes (cf. p. 489).

The sclerosis is not always obvious to the naked eye, nor until the cord has been hardened, so that one can understand how formerly observers declared the cord healthy, when locomotor ataxy had been present during life. The negative results, however, obtained by competent histologists with modern methods cannot be easily set aside, and there seems good reason to believe that tabes symptoms may depend, not only on the classical lesion of the cord, but also in certain exceptional cases on primary atrophy of the posterior roots of the lumbar and sciatic plexus. Whether other cases which have been called "pseudo-tabes" are functional neuroses which only simulate the true disease, or whether they have a peripheral origin, are still open questions.

Pathology of tabes.—Accepting the lesion in the cord, we have still the interesting but difficult question of its physiological connection with the symptoms above described. It has been shown that inability to stand or walk steadily with the eyes shut is no more than an effect of anæsthesia of the lower limbs. Moreover, a similar doctrine is held by some authorities with regard to the failure of co-ordination itself. Basing his views upon the acknowledged fact that guiding sensations contribute to the due execution of movements, Leyden maintains that ataxy is the consequence of interruption in the transmission of such sensations along the cord.

It must be admitted that some plausible arguments can be brought forward in favour of the doctrine in question. One is that the most obvious lesion is seated in a part of the cord which is (or was) believed by physiologists to convey afferent impulses. Another is the frequency with which a more or less considerable degree of anæsthesia is present, even at an early

period. And if there are cases in which cutaneous sensibility appears to be perfect, it may be replied that in many of them the sensibility of the muscles and tendons and joints has not been tested, and that this is no less essential for the even and regular execution of muscular movements. The fact that it is impossible to elicit tendon-reflexes, even at the commencement of the disease, may be pressed into the same argument.

Nevertheless, it would seem that there are facts which make it impossible for us to accept Leyden's views. One is that some cases, at least, of ataxy are unattended with any discoverable anæsthesia or defect of muscular sensibility. Both Friedreich and Erb speak positively on this point. Again, there is no close correspondence in individual patients between the degree of impairment of sensation and that of disorder of co-ordination. Lastly, there may be absolute anæsthesia without the slightest irregularity in the movements of the limbs.

A case in point was recorded by Späth in 1864, and was ten years later followed to an autopsy by Schüppel. The patient had for more than twenty years lost sensation in his arms and hands, and for six years in his feet. He was quite unconscious of the position of his limbs; and when they were moved by another person he knew nothing of it. Yet he could walk steadily, without support, and tolerably fast. When asked to raise his foot to a certain height with his eyes shut, he did it with a perfectly even and regular movement. After death the whole length of the cord was found excavated in the centre; the posterior columns in the cervical region were completely destroyed; the anterior columns were everywhere normal. It is particularly to be noticed that in this instance the muscular sensibility was absent, as well as that of the skin.

But if ataxy is not due to interruption of afferent or sensory impulses, how is it caused by a lesion situated in the posterior columns? Most writers seem to suppose that these columns may possess the special function of conveying impulses from a co-ordinating centre above, in the medulla oblongata or pons, to the motor nuclei in the cord. But it seems clear that co-ordination, instead of being affected by a single centre, must require a very complicated apparatus, probably consisting of several parts situated in different regions of the cerebro-spinal axis. We have seen that the reflex movements which are performed by the spinal cord independently of the brain are never entirely without co-ordination, and that sometimes they are co-ordinated in a very complex way. One can hardly doubt that the machinery which is brought into operation under such circumstances is also made use of when similar movements are excited by the will.

Moreover, we must remember that what is observed in ataxy is by no means an entire absence of co-ordination, such as would occur if the volitional impulses passed straight down to a group of muscles, without relation to any others. On the contrary, it is probable that the failure is very often of the slightest possible kind. Scarcely appreciable irregularities in the force which the muscles severally exert, or even in the intervals of time at which they are increasingly brought into action, would account for the symptoms in some well-marked instances of the disease. No wonder, then, that lesions of the proper motor tracts of the cord do not cause ataxy. We should rather expect it to be due to some affection just touching the outskirts of these tracts so as to injure them only very slightly. A sclerosis commencing in the fasciculi cuneati of the posterior columns seems to be just such a lesion as might produce this effect.

Again, it is certain that even in the earliest stage of the disease other parts besides the posterior columns must be involved. In no other way can one explain many of the prodroma. What is to be said as to the origin of the atrophy of the optic discs? Pathologically the morbid change in them is identical with that which is going on in the cord itself. But why should it occur in cases of tabes, and not in those of diffused myelitis? And, further, why should amaurosis from this cause often precede all spinal symptoms by an interval of several years, so that Charcot believes that the majority of the female patients admitted into the Salpêtrière for simple atrophy of the discs become sooner or later the victims of ataxy? The affections of the ocular muscles are supposed by Erb to be due to slight lesions of the nerve-roots or of their nuclei in the pons and bulb, but he does not attempt to show how it is that only motor structures are attacked, nor why the nerves concerned in moving the eyeballs suffer more than any others. As regards the last point, indeed, we may perhaps see an explanation in the delicate way in which the muscles in question are naturally balanced against one another. This renders the slightest impairment of the power of any one of them at once obvious to both the physician and the patient. The same degree of paresis elsewhere would be altogether incapable of recognition. It is said, however, that actual paralysis of the facial muscles, or of those concerned in mastication, has sometimes been observed in tabid patients.

The arthropathy which is now and then seen among the prodroma of tabes is believed to depend upon an atrophic change in the grey matter of the anterior cornua. Joffroy and Westphal have each made observations which directly confirm this opinion.

On the other hand, the boring and flashing pains are doubtless dependent upon the morbid changes in the fasciculi cuneati, *i. e.* the posterior root-zones, and the nerve-roots immediately adjacent.

There is abundant proof that in the more advanced stages of the disease the morbid process may extend in all directions within the substance of the cord. Changes in the lateral columns (the crossed pyramidal tracts) were long ago noticed by German observers, and may explain the spastic symptoms which sometimes come on in the latter stages of paraplegic ataxia.

Charcot says that the nerve-cells of the anterior cornua may be destroyed so as to cause atrophy in the corresponding muscles. When there has been an absolute loss of power in the lower limbs, almost the whole thickness of the lumbar cord may be wasted, tough, grey, and translucent.

The fact that even the prodroma of locomotor ataxy can be accounted for only on the supposition that changes exist in structures far distant from the posterior columns of the cord, makes it surprising that a definite boundary-line should be traceable between it and other spinal affections. As with Multiple Sclerosis (the disease to be described in the next chapter), it seems that the clinical features of the disease are far more uniform than would have been anticipated by the morbid anatomist. Charcot, however, admits that pains precisely like those that occur in the early stage of tabes may be observed in multiple sclerosis, in general paralysis, in chronic alcoholism, and even in diffuse myelitis or compression-paraplegia.

So difficult is it to connect the symptoms of tabes with its morbid anatomy, so few, after all, are the cases which are watched during life and satisfactorily investigated after death, and so complicated and various are both the clinical symptoms and the local distribution, that some experienced

physicians even now doubt the reality of the connection between locomotor ataxy and posterior sclerosis. (Wilks, 'Brit. Med. Journ.,' 1884, i, p. 886.)

But even if locomotor ataxy is not invariably coincident with sclerosis of Burdach's columns, the combination of disturbed movements, impaired sensations, loss of knee-jerk, defects in the eye and its muscles, and peculiar neuralgic pains, make up a "complex of symptoms" which has a beginning, a middle, and an end, and may therefore from a clinical point of view be called a disease.

Ætiology.—Among tabid patients the preponderance of males over females is very marked, but the proportion is variously stated by different observers, as 8 to 1 (Erb), 3½ to 1 (Cyon), 2½ to 1 (Carré, Schulze). Eulenburg found in 149 cases, 128 men, including 2 youths under twenty and 5 men over fifty, *i. e.* 6 males to 1 female. Among 83 tabid patients in Guy's Hospital there were 75 men and only 8 women.

Tabes very rarely occurs in persons under twenty years old, or begins in those who have passed the age of fifty. The case of an old gentleman of eighty is mentioned by Trousseau; but it is not stated how long he had been a sufferer.*

Some writers assume a family "neuropathic" disposition. One patient of Trousseau's had an uncle and an aunt insane, a brother ataxic, and a brother hemiplegic; another patient was the son of a man who committed suicide, and two of his sons laboured under certain peculiar nervous affections. In many cases, however, no predisposition to "nervous diseases," could be traced; and there can be no real pathological connection between a primary sclerosis of the cord on the one hand, and such diverse pathological conditions as paraplegia from tubercular disease of the vertebræ, hemiplegia from atheroma or Bright's disease, and paralysis from syphilis or drink.

Carré has recorded the direct transmission of tabes itself in a family of which the grandmother, the mother, her seven children, and eight others of her relations were all attacked. But such instances are very rare; and, as we shall presently see, it is possible that they may belong to an independent malady (*v. infra*, p. 539).

With regard to the exciting causes of tabes, there is equal uncertainty. Sometimes it has followed an attack of fever, acute rheumatism, or pneumonia; sometimes it has taken the place of paraplegia after diphtheria, as in cases recorded by Jaccoud and Erb. It occasionally follows injuries, not merely of the spine, but a fracture of the thigh, or a fall on the abdomen. In some cases it has been ascribed to a severe chill, as from falling into water, or sleeping on damp ground; to over-fatigue, as in soldiers after forced marching; to prolonged mental anxiety or distress; or, lastly, to venereal excesses—the supposed cause of tabes dorsalis before its symptoms were defined or its anatomy known. The wars at the beginning of the present century seem to have given rise to numerous cases of ataxy among the French and German soldiery; it is difficult to say exactly how campaigning sets up the affection, possibly by the combined operation of several of the causes above mentioned. The greater liability of men between the ages of thirty and fifty to these various morbid influences is

* Of eighty patients in Guy's Hospital one was under 20, three between 20 and 30, twenty-seven between 30 and 40, thirty-four between 40 and 50, and eighteen over 50 years of age. But in many of them, especially the older patients, the disease had begun several years before their admission into the hospital.

perhaps the reason why male adults are especially apt to suffer from ataxy; or perhaps the liability of male adults to tabes may explain its comparative frequency among soldiers.

Tabes was first definitely connected with *syphilis* by Fournier, who believed that among 102 tabid patients 74 had suffered from that disorder. Erb strongly supported this theory, and his statistics gave the proportion 61 in 99; Vulpian found 15 in 20, Buzzard 49 in 100, Gowers 29 in 50, and some writers made the proportion higher still. Thus Ross, among 20 cases of tabes, could only exclude syphilis as an antecedent in a single one. (See on this point 'Trans. Internat. Med. Congr. 1881,' pp. 32—42.)

Diagnosis.—From the nature of the early symptoms of tabes, it is evident that its diagnosis at that period of the disease is often a matter of extreme difficulty. Premonitory pains would be probably dismissed as "neuralgic" or "rheumatic," but in many cases of this kind a careful investigation would elicit other indications of the disease. There may be a slight squint, a contracted state of the pupils, or an absence of knee-jerk; or the patient may totter a little when told to walk, or to stand with his eyes shut and his feet close together. This last is a most valuable sign when we are in doubt as to the presence of any spinal affection, but much less so as between tabes and other diseases of the cord.

When the complaint is fully developed, its diagnosis is generally easy. Pronounced paralytic symptoms, with wasting of muscles, may sometimes cause one to overlook the previous existence of ataxy. Again, when there is disseminated multiple sclerosis, and the posterior columns are also attacked, it may be impossible to assign the case to one affection rather than to the other. We have seen that tabes not infrequently occurs in association with general paralysis of the insane, so as to puzzle those who happen to be more familiar with one than with the other of these two diseases.

The failure of co-ordination which accompanies disease of the cerebellum does not seem to be likely to be mistaken for the ataxia of tabes. It may generally be distinguished by the absence of other spinal symptoms, and by the presence of headache, giddiness, vomiting, optic neuritis, epileptiform attacks, and the various other signs of encephalic lesion. Moreover, the so-called cerebellar ataxy is not attended with the peculiar mode of walking above described, but with a reeling gait, like that of a drunken man.

Prognosis.—Notwithstanding what has been said above of the relentless progress of the disease, we must remember, first, that this progress is always slow, often exceedingly slow, and frequently interrupted for an indefinite period; secondly, that it does not lead to death unless one of the complications above noticed supervene. Probably most tabid patients die of phthisis, because that is the commonest of diseases, and some of disease of the heart; many of latent pyelitis or consecutive Bright's disease, from vesical complications; others again from the bedsores of paraplegia, from the effects of secondary cerebral or spinal disorders, or from accidental injuries; and others from common acute diseases which come on accidentally, as pneumonia or bronchitis. Great improvement often takes place under judicious general management, and although patients are not cured of the disease, they are relieved of its most distressing symptoms.

As a rule, the duration of tabes varies between six and twelve years,

and it may last twenty or thirty years. Some writers have described an acute form of tabes, and one case was so diagnosed in a woman who died in Guy's Hospital six weeks after admission, and about ten months from the beginning of her illness. But in this instance there was softening of the anterior columns in the lumbar region, as well as sclerosis of the posterior columns.

Erb mentions two cases, in each of which almost complete recovery took place. One patient afterwards held a Government appointment for several years; the other, who had been unable to get about without help, and had suffered from incontinence of urine with cystitis, regained the power of walking for three or four hours at a time, and of holding his water for five or six hours; he married and took the command of an ironclad frigate.

The course of the disease is not always steadily progressive; it is often quiescent for a long period. Generally it is better in the summer than in the winter. In some cases, it scarcely seems to shorten the patient's life.

Treatment.—When tabes is fully developed it rarely is cured by treatment of any kind.

The general management of the patient is of great importance. He must be carefully protected from cold and damp by flannel underclothing. He must avoid all bodily and mental exertion. Dr Radcliffe thinks it advisable that crutches should be used in the early stages, so as to save the lower limbs as much as possible. It has been suggested that maintaining absolute rest in bed might favour the subsidence of the disease, and Dr Weir Mitchell brings positive evidence in favour of this plan. Dr Gowers recommends a sea voyage. Those who can afford it will find great benefit from spending the winter and spring in the South of Europe, or still better in the Azores or the West Indies. *Abstineto tabidus a vino et venere.*

Erb recommends galvanism applied as a continuous current to the spine. He uses a moderate number of cells, for three to six minutes at a time, once daily. Of sixty-six cases thus treated, twenty-five received no benefit, forty-one were more or less improved. He also galvanises the peripheral nerves.

Locomotor ataxy is among the maladies for which persons resort to the various spas. Almost all writers are agreed that hot baths are injurious, many believe that cold baths are useless. Erb says that any temperature above 58·5° F. is undesirable, and that the patient should bathe only once in two or three days, and remain in the water not above fifteen or twenty minutes. Nauheim and Rehme are the places which seem at present to have the highest reputation. Peat baths are also recommended. But the figures given by Erb appear to show that the "cold-water cure" with packing, friction, and douches is quite as useful: of nineteen patients treated in this way, sixteen are said to have been benefited.

Among the symptoms of tabes, the pains most need relief. Sinapisms, blisters, liniments of chloroform or belladonna, veratria ointment, may be of some use; but often one cannot avoid frequent injection of morphia. Of late years *antipyrin* has been used with much success, and the writer is disposed to believe that this is the most useful application of the drug. *Exalgine* (methyl-acetanilide), recently recommended by Dr Fraser of Edinburgh for facial neuralgia, would probably also be of service. ('B. M. J.,' Feb. 15, 1890.)

As a specific alterative, the drug of most value is perhaps the nitrate of silver; it often fails entirely, but sometimes does great good. We generally

order a quarter of a grain three times a day. Belladonna and bromide of potassium seem to be useless, and strychnine to be injurious. Calabar bean, arsenic, and ergot in early cases, may perhaps do good.

When tabes follows syphilis, we should certainly give the patient a fair trial of *antisyphilitic remedies*. No doubt they often fail, and in the later stages of the disease probably do more harm than good, but the only cases of tabes seen by the writer which were cured were treated by mercury.

One was that of a man, about forty-five, who was admitted into Guy's Hospital with marked ataxy, loss of knee-jerk, and other symptoms; indeed, myosis was the only important one absent. He had the signs as well as the history of syphilis, acquired long before. Under a mercurial course he improved so much that he went out, walking well, free from pain, and in fact cured, though the knee-jerk had not returned. He stated while in the ward that he had some years before suffered from similar symptoms (ten years or so after primary syphilis), and had been cured by the same treatment. Another case is that of a patient who has been under observation for five or six years. He had syphilis years ago, and still has occasional tertiary sores on one heel. The worst symptoms of tabes have disappeared under mercury and iodide of potassium, but he still has minutely contracted pupils and loss of knee-jerk. Neither case is conclusive, but this method is well worth trying when we know that syphilis preceded the nervous symptoms.

Mechanical *stretching* of the great sciatic nerves has been used as a remedy for tabes. It was first performed by Langenbuch with apparent success; but when the patient died, the cord was found healthy. On the whole, the good effects seem to be doubtful, and the drawbacks and dangers undoubted. See an interesting paper by Dr Cavafy, with eighteen cases, beside one of his own ('Brit. Med. Journ.,' Dec. 10th, 1881); also Mr. Bowlby's record of cases (loc. cit. p. 360).

Another somewhat analogous plan of treatment has lately been extensively tried. It consists in *suspension* of the patient by the head, so that the weight of the body pulls upon the attachments of the cord to the spinal column by its membranes and nerve-roots. This method was introduced by Dr Motschukowsky, of Odessa, and has been tried on a large scale by Charcot and other physicians on the Continent, in England, and in America. Great care is needed in carrying it out, for in more than one case it has caused death, and in one of these the autopsy showed the absence of posterior sclerosis. The suspension must be gradual, and at first for less than a minute at a time.

Many instances have been recorded in which the lightning pains of tabes have disappeared under this treatment, while faculty of locomotion and virile power have returned. But in many more these effects have been absent or transient; and the spontaneous variations in the symptoms of this disease during its slow and irregular course are so great, that improvement in symptoms, and particularly in subjective symptoms, must be accepted with great caution as proof of the efficacy of this and of any other plan of treatment. A patient on whom the writer carried out suspension said that he was greatly benefited; but the improvement was very doubtful to those who watched the case, and he had been equally gratified by the good effects of a few grains of salt, given as a control experiment while his symptoms were being recorded. In the absence of conclusive evidence of the value of the method,

interest attaches to experiments made on the dead body, which seem to prove that its effect is to straighten the vertebral curves, and to relax rather than stretch the spinal cord.* It may have some effect possibly on meningeal adhesions, possibly on the circulation of the cord; but if so we cannot say beforehand whether either would be beneficial or the reverse. On the whole, it seems at present likely that the method of suspension will be abandoned as of doubtful service, and not unattended with risk.

FRIEDREICH'S DISEASE.†—Friedreich first described in 1863, and more fully in 1876, an *hereditary* (or rather "*family*") form of tabes which presents several peculiar features. He recognised it in only three families; in each of them it attacked in succession several children of the same parents, in all nine patients, of whom seven were girls. It began unusually early, at or near the age of puberty, between the thirteenth and the eighteenth years. Among eleven cases Rütimeyer found seven boys and four girls, the ages being all under puberty (1883). Since then further observations have shown that this form of tabes occasionally occurs in two generations, much more often in several brothers and sisters; that it begins in childhood as early as four, at puberty, or in early adult life as late as twenty-four; and that girls are almost as often affected by it as boys.

The disease is attended with remarkably little disturbance of sensation; the prodromal pains in the limbs and the later girdle-sensation round the body are absent or slight, and there are none of the ocular symptoms of tabes.

A peculiar form of *nystagmus*, however, is sometimes present; it is characterised by occurring only when the patient endeavours to fix his eyes upon an object before him; the movements are always bilateral, and are comparatively slow, being repeated two or three times in a second.

Ataxia begins in the legs, but the upper limbs show a loss of co-ordination at an early period.

In every instance there has been a remarkable disorder of *speech*. The utterance is described as having been at first slightly lisping (Calloud), then as irregularly interrupted and stammering, and finally as almost unintelligible. It is altogether unlike the slow accentuated articulation of a patient suffering from multiple sclerosis. The skin and joints are unaffected. Knee-jerk is absent. The senses and the mental faculties are perfect.

Choreiform movements of the face and limbs have been observed sometimes as the first symptom, so that the disease has been mistaken for chorea.

The duration of these cases has been very long; in one instance it was more than thirty years. A curious circumstance is that five of the patients died of enteric fever.

Clinically it resembles insular sclerosis or functional spasmodic disorders as much as it does ordinary tabes.

Sclerosis of the posterior columns has been found after death, but it has been combined with sclerosis of the direct cerebellar and of the lateral columns. In two cases (Friedreich, and Kahler and Pick) the entire cord was remarkably small.

The author had once under observation a typical example of Friedreich's ataxy. The patient, a medical man, was first noticed to be uncertain in

* See Dr Cagney's paper, 'Trans. Roy. Med.-Chir. Soc.,' Jan., 1890.

† *Synonyms.*—Hereditary ataxy—Juvenile ataxia—Hereditary tabes in children—Hereditary ataxic paraplegia (Gowers)—Early tabes with nystagmus occurring in families.

his gait when about sixteen years old. He was one day walking across a plank in a house that was being built, when he tottered; afterwards he remembers that he had to be careful not to go near the edge of the path where it was raised above the road. But he came to the hospital as a student, passed his examinations, went into practice, and took a wife. At the age of about twenty-five he was obliged to give up his profession on account of increasing inability to walk or ride; he became unable to write, and his speech became laboured and thick. In 1878, when he was thirty, he could just walk from one room to another with assistance; there was even then but little impairment of sensation in his feet; when he moved his lips in speaking a large number of the facial muscles were thrown into action, so that the mouth became drawn outwards into a meaningless smile; the words were tolerably distinct, but some syllables were slurred over, and others pronounced too strongly. The nystagmus was very obvious when he was told to direct his eyes to either side. He was a member of a highly neurotic family, and one sister suffered from some form of paralysis.

We have since had three brothers in Guy's Hospital suffering from this juvenile family type of ataxia with nystagmus. The case of one of them is reported in the forty-fourth volume of our 'Reports' (1887), and is identical with one of the five cases in the same family recorded by Dr Gowers in the fourteenth volume of the Clinical Society's 'Transactions.' One of them died under the late Dr Moxon's care. Sections of the cord were made by Dr Pitt, and are described and figured by him in the article referred to. They showed sclerosis of the posterior columns (both Burdach's and Goll's), with similar change in the crossed pyramidal and cerebellar tracts. The anterior columns, which also have been sometimes found affected, were free, and the grey substance normal. The lesion was most marked in the cervical and dorsal regions, but the cord in its whole length was remarkably small, as if from congenital atrophy.

Dr J. A. Ormerod has published a critical digest of the recorded cases of this remarkable form of disease in 'Brain' for April, 1884; and Dr Bury in the ninth volume of the same journal. Dr Everett Smith (quoted by Gowers) has collected no less than fifty-seven cases in the 'Boston Medical and Surgical Journal' for Oct. 15th, 1885.

INSULAR SCLEROSIS*

Tremor oritur a spiritibus animalibus per apertas valvulas in oppositos musculos influentibus, qui spiritus . . . istas non claudunt; ut ventus semiapertam januam non claudit.—JOH. DOLÆUS, 'Medica dogmatica,' 1691.

History—Anatomy—Symptoms—Ætiology—Diagnosis—Prognosis and treatment. Comparative frequency of diseases of the spinal cord in hospital practice.

IN the great illustrated work of Cruveilhier on pathological anatomy, published between 1835 and 1842, there are figures taken from four different patients representing the spinal cord affected with what he termed "grey degeneration," in the form of patches scattered irregularly through its substance. In two of these cases he also gave the clinical features of the disease. About the same time Carswell figured the same lesion in his 'Atlas of Pathological Anatomy' (1838), and Marshall Hall described the characteristic symptoms in his 'Diseases of the Nervous System' (1841). Afterwards various writers from time to time referred to similar cases, but it was not until about the year 1866 that a series of observations were made at the Salpêtrière, from which it results that the disease in question is characterised clinically by a remarkable and definite group of symptoms, so that it can often be diagnosed with certainty. In these researches Charcot took the principal part. The subject was soon taken up in Germany, but in England it seems to have been neglected until in 1873 the late Dr Moxon published a case in the 'Lancet,' and in 1875 a paper containing eight cases in the 'Guy's Hospital Reports.'

Cruveilhier's drawings show that the bulb and the pons are affected as well as the cord, and the same morbid change has since been found in the hemispheres. Insular sclerosis might therefore with equal justice be placed among cerebral diseases; indeed, several of its symptoms are cerebral. Hence its most appropriate place seems at present to be between diseases of the cord and those of the brain.

Some writers have wondered that so remarkable a disease so long remained unknown, but its slow and hopeless course renders it little likely to go on to its fatal termination within the wards of ordinary hospitals. The author was unable to find a single case which could be assigned to disseminated sclerosis in the pathological records of Guy's Hospital between 1854 and 1873. In the ten years 1880 to 1889 inclusive, we had twelve cases.

Histology.—As a rule, the morbid change is at once obvious when the nervous centres are examined in the *post-mortem* room. Bourneville has, however, recorded one case in which they appeared to be healthy until the microscope was used. The patches of sclerosis are rounded or elliptical or

* *Synonyms.*—Multiple cerebro-spinal sclerosis—Disseminated sclerosis—*Fr.* Sclérose en plaques (Vulpian)—Sclérose en îlots multiples et disseminés (Liouville)—*Germ.* Multiple inselförmige Sclerose (Leube)—Herdweise Sclerose.

irregular in form. In the cord they come to the surface, and are sometimes seen through the pia mater. In the brain they affect the white substance of the hemispheres and scarcely ever penetrate into the cortex, but they are often visible on the surface at the base. In the basal ganglia, the pons, and the cord they show no tendency to spare the grey matter, or to affect one column or cornu more than another. Hence Insular Sclerosis is not a "systemic" disease in its distribution, nor focal, nor transverse, but essentially indiscriminate or scattered.* The grey patches are often scattered in large numbers throughout the white matter of the hemispheres. The cerebellum seldom contains many of them. A similar change may be present in the olfactory bulbs and in the roots of the various cranial and spinal nerves. In the peripheral trunks it has not yet been recognised: Moxon found the brachial plexus in one case normal on each side.

The patches generally feel hard, but recent ones are said to be softer than the rest and of a deeper grey tint, whereas the older ones are yellowish grey and less translucent. They become pinkish when exposed to the air. They may either project somewhat above the cut surface, or lie at the same level, or be slightly depressed. They vary from a microscopic minuteness up to the size of a hazel-nut or more. Histologically they present the characteristic appearances of chronic interstitial or grey degeneration (p. 441). Charcot says that there are fewer corpora amylacea, and that a distinction is afforded by the way in which naked axis-cylinders persist even when the neuroglia has become highly fibrillated, but the last point is contested by Erb. It is to be observed that in thin sections the affected parts are found not to be so sharply defined at their edges as they appear to the naked eye; on the contrary, the sclerosis fades off very gradually into the healthy tissue. Moxon remarked that granule-cells are more numerous at the circumference of the patches (and even in the apparently normal brain-substance beyond) than towards their centres. Deiters' cells and corpora amylacea are present.

Symptoms.—That the clinical features of disseminated sclerosis should vary in different cases is no more than we should expect from the irregular distribution of the patches, which would account for the utmost irregularity in the symptoms. Charcot, indeed, speaks of it as polymorphous in its clinical aspect. He and other French writers describe, in addition to the "cerebro-spinal" form of the disease, separate "spinal" and "cerebral" forms, but it is admitted that such distinctions can seldom be made at the bedside. Moreover, notwithstanding individual variations, the symptoms present a degree of uniformity which is very remarkable. This uniformity Dr Moxon regarded as "a constant average result of the numerous points of disease;" but the explanation leaves much unexplained.

We may refer disturbance of the special senses to sclerosis of their nerves, spasms to implication of the lateral columns, and mental symptoms to cerebral lesions; but neither in this disease nor in spastic paraplegia could we have predicted the symptoms from the anatomical lesions.

The tremors, the nystagmus, and the peculiar speech—the most constant symptoms—are quite unexplained.

* See an excellent plate in Dr Bramwell's work, which shows the distribution of the patches of sclerosis throughout the cord in a well-marked case, and the way in which they stain with carmine. This is an example of the larger-sized islands. In Dr Moxon's paper in the 'Guy's Reports' (1875) is a coloured drawing of the centrum ovale, with insular sclerotic patches, and a microscopic section of the cord.

Early prodromal symptoms are sometimes observed which, according to Dr Buzzard, closely simulate hysteria—loss of power or numbness in one limb, pins and needles, &c.

The first developed symptom is a sort of *tremor*, which until recently was confounded with paralysis agitans. There are, in fact, records of two cases diagnosed as examples of that affection by Skoda and by Hasse respectively, in which patches of sclerosis in the nervous centres were discovered after death. Careful observation, however, has shown that in paralysis agitans the trembling movement is less extensive, more regular, and more rhythmical than in insular sclerosis. In the latter disease, when the hand is raised, the oscillations increase in amplitude as it gets further from the side, until they greatly embarrass and disturb the patient. If he is asked to carry a cup to his lips it becomes more and more violently shaken until at last it is dashed against the teeth, so as perhaps to spill its contents. In slight movements the tremor is not so marked; the handwriting, although shaky, long remains legible.

There is no agitation of the muscles as long as they are at rest and supported. When the patient is lying in bed, one could not tell that anything is the matter; but as soon as he is asked to sit up, the arms, and then the head and the neck, begin to oscillate. When he is resting in a chair the arms are quiet, but the head may still continue to show a slight tremulous movement. If he attempts to get on his feet the whole trunk and all the limbs become violently shaken, so that in severe cases standing is out of the question. Mental emotion or excitement aggravates the tremor considerably. According to Erb there are some cases in which it continues even when the patient is lying still, but this is altogether exceptional.

Charcot has suggested that this remarkable symptom depends upon the persistence of naked axis-cylinders in the parts affected with the sclerosis, and conceives that the transmission of volitional impulses may become interrupted and, as it were, jerking; but such a view appears unlikely. Ordenstein is disposed to think that the tremor depends in some way upon the presence of patches in the pons and still higher in the motor tracts, and Erb says that an analysis of twenty-two recent cases tends to support the notion of the connection of this symptom with abundant islets in the mesencephalon.

A second characteristic symptom of disseminated sclerosis is a peculiar *affection of the speech*. The pronunciation is slow, accented, laboured, as if the utterance of each syllable was a great effort. And yet it is not distinct; Charcot says that the letters L, P, G, are especially apt to be slurred over; and sometimes, though rarely, two or three syllables are run together. German writers describe the articulation as "scanning," each syllable being pronounced separately. In advanced stages speech may become quite unintelligible. Erb further remarks that the voice is pitched in a monotone; or, as in one case that came under his observation, that there may be a rhythmical alternation of notes at a definite musical interval. Leube found with the laryngoscope that the vocal cords, although capable of closing the glottis, were yet apt to relax, and liable to changes of tension ('Deutsches Archiv,' 1871).

Thirdly, *nystagmus* is commonly present. It, however, differs somewhat from the ceaseless oscillation of the eyeballs with which ophthalmic surgeons are familiar. As Dr Moxon pointed out, it is absent so long as the eyes are at rest, showing itself only when they are directed to an object. In

other words, it is identical with the affection which is observed in Friedreich's hereditary ataxy (see p. 539); indeed, both Friedreich and Erb have suggested that the anatomical lesion may be the same, but rather as a matter of speculation than from direct observation.

In addition to these distinctive symptoms, there are others which belong to disseminated sclerosis in common with other diseases.

Subjective sensations of *numbness* and other paræsthesiæ are not uncommon, although they were absent in Dr Moxon's eight cases; anæsthesia, or impairment of tactile sensibility, can seldom be made out.

The gait at an early stage is often *spastic* in character. The cutaneous reflexes are usually normal, but sometimes they are increased. Knee-jerk is exaggerated, and clonus often present. Afterwards there is a marked tendency for the lower limbs to become rigidly extended and adducted; this condition being at first transitory, but afterwards permanent. Moxon mentions that one of his patients was obliged to sit in an elbow-chair, so that when her legs stiffened she could hold on to the arms and save herself from sliding down on to the floor. Such early contractions are painless, but at a later period a painful flexion of the limbs is not infrequent. In ordinary cases there is no reaction of degeneration, and the muscles react to both currents until they finally undergo atrophy.

The characteristic symptoms of locomotor *ataxy* are now and then present in disseminated sclerosis; this is supposed to depend upon the existence of patches in the posterior columns of the cord.

After a long time complete *paraplegia* usually develops itself. The functions of the pelvic organs are at first but little interfered with. Constipation is frequent; and Moxon refers this in part to weakness of the abdominal muscles. The sexual organs retain their powers, and there is no retention of urine until the latter stages of the disease.

Among other *cephalic* symptoms amblyopia often occurs, with narrowing of the field of vision and achromatopsy, and transient *diplopia* is not infrequent at an early stage of the disease. Charcot insists on the fact that the impairment of sight rarely goes on to complete amaurosis, even when the optic nerves have been found sclerosed in their whole thickness; he refers this to the persistence of naked axis-cylinders in the midst of the diseased tissues. The optic discs are generally normal unless there is total blindness; in the latter case they have sometimes been found in a state of white atrophy. Any degree of optic neuritis with disturbed vision would be an important indication of an early stage of this singular disease. Headache, giddiness, and sleeplessness are not uncommonly present.

The spirits are often depressed, and the *memory* and *intelligence* become gradually impaired. The patient bursts into uncontrollable laughter, or sheds tears without any cause. Charcot insists on a peculiar *facies*; the expression is, he says, vague, uncertain; the lips droop and are half opened; the features have an air of dulness or stupidity. Sometimes there is an actual insanity. Charcot mentions two patients who exhibited the *délire des grandeurs* supposed to be characteristic of general paralysis; in others there has been melancholia, with refusal of food.

A curious feature, which is observed in about one fifth of the cases of disseminated sclerosis, is the occurrence of attacks of stupor, followed by transitory hemiplegia. They are attended with flushing of the face, a rapid pulse, and a temperature raised to 104° or even 106°. The coma lasts for a day or two, and then passes off into sleep. Sometimes, however, a

seizure of this kind is directly fatal; one of Moxon's patients died so in about twenty-four hours. Such an attack is said always to lead to an aggravation of the general symptoms of the disease, even when it is recovered from.

Lastly, in some exceptional cases atrophy of muscles is observed, affecting the upper or lower limbs, the face, or the trunk. At the same time their electrical excitability, which ordinarily remains normal, may be lowered; and the natural reaction is doubtless replaced by the "reaction of degeneration." Charcot says that the characteristic symptoms of bulbar paralysis sometimes show themselves, and dysphagia or paroxysmal dyspnœa may then be the immediate cause of death.

It is obvious that many of the above symptoms of insular sclerosis are due to the disease invading the lateral or the posterior columns, the anterior cornua or the nuclei in the bulb and mesencephalon, so as to produce the symptoms which belong to tabes, spastic or atrophic paralysis, and so on. The paraplegic period, again, with bedsores, retention of urine, and other pelvic symptoms, belongs to the last stage of all chronic diseases of the cord.

Ætiology.—Disseminated sclerosis is now ascertained to be equally frequent in either sex, although Charcot found twenty-five females to nine males among the first thirty-four cases which he collected. The age at which it most frequently develops itself is said to be between twenty and twenty-five years, but it has been several times observed at puberty, and instances of its occurrence in childhood have been recorded. It has not hitherto been known to begin in persons over forty or forty-five years old. Now and then it has appeared to be hereditary or has occurred in two children of the same parents.

Like other chronic affections of the cord, it has been ascribed to "chills," to falls and blows on the head, and to moral shock, mental excitement, or, as it is now called, "worry" and "over-strain." Bauwinkel records a case in which a man fell into water and allowed his clothes to dry upon him, three days before the first symptoms of insular sclerosis appeared. Charcot cites instances in which the disease began during convalescence from enteric fever, cholera, or smallpox. All that we can conclude is that these several antecedents do not *protect* a person from insular sclerosis.

Diagnosis.—This is not invariably, or even generally, an easy matter. Charcot says that trembling movements, precisely like those which are present in this disease, may occur not only in mercurial poisoning (when the history will in most cases remove all doubt), but also when the lesion is a "chronic cervical meningitis with cortical sclerosis," and even where it is a "primary or consecutive sclerosis of the lateral columns." The presence or absence of the other characteristic symptoms of these affections must guide the observer to a decision so far as they are concerned.

The diagnosis from paralysis agitans is not the most difficult, for that disease occurs in older patients, the tremors continue when the muscles are at rest, and affect the hands more than the feet, their amplitude is smaller and more uniform, and their rate is generally quicker. Moreover, in paralysis agitans the shake precedes the palsy, whereas slight loss of power in walking is usually the earliest symptom of insular sclerosis, as in a typical case recorded in 1875 by Dr Goodhart, in a woman of thirty-eight, with characteristic lesions after death ('Path. Trans.,' xxvii, p. 17).

Diagnosis of insular sclerosis from tabes, from Friedreich's ataxia, from

spastic paralysis and bulbar palsy, probably means only that we must distinguish clinically in mixed forms of disease the characters of one type which are complicated by some usually associated with another. Corresponding coincidences of posterior, lateral, anterior, or bulbar sclerosis with disseminated cerebro-spinal sclerosis have been found *post mortem*.

Cases presenting during life the characteristic speech, nystagmus, tremors, and increased knee-jerk have after death failed to show insular sclerosis of the brain and cord. Some of these were probably cases of general paralysis of the insane. (See Dr Bristowe's cases in his collected papers on diseases of the nervous system).

Great caution is required to avoid mistaking hysteria for disseminated sclerosis in women; and Moxon says that he has seen several patients about whom he has for a time been in doubt, but who have before long completely recovered. See also Dr Buzzard's instructive address before the Neurological Society on the "Simulation of Hysteria by Organic Disease of the Nervous System" ('Lancet,' Jan. 23, 1890, and 'Brain,' Feb.).

When tremors are absent, the case may appear to be an example of some other spinal affection. Charcot supposes that in these cases the symptom in question was present at an earlier period; but Erb refers to several in which it was wanting throughout the whole course of the disease. Thus he cites Westphal and Killian as having recorded instances in which the only symptoms were dementia and paralysis with contractions of the limbs.

Course, prognosis, and treatment.—This remarkable disease usually begins insidiously, with slight giddiness, affections of sight or hearing, weakness in the legs, and difficulty in walking. As an exception it begins more suddenly, perhaps with an epileptiform fit.

The course of disseminated sclerosis is slowly but irregularly progressive, although remissions in the symptoms may occur spontaneously or under treatment. The average duration of the disease is said to be from five to ten years, the most rapidly fatal termination being in one year from the commencement, and the latest at the end of seventeen years. This, however, partly depends upon the nature of the symptoms. Charcot says that cases in which spinal symptoms alone are present may go on for twenty years or longer. If death does not occur in one of the ways already mentioned, it is generally by the supervention of some intercurrent disease, such as pneumonia, pleurisy, dysentery, œdema of the glottis, or more frequently by ordinary tubercular phthisis.

Few remedies have been found of any service. Charcot thinks that the administration of strychnia or of nitrate of silver has sometimes diminished the tremor and the weakness of the lower limbs, but only for a time. Some observers have seen transitory benefit result from the cold-water treatment, from galvanism, or from the subcutaneous injection of arsenic. Many of the drugs given probably do harm. The only rational treatment is to alleviate individual symptoms, and to make the patient as comfortable as he can be made.

Before passing on to our next subject, Diseases of the Brain, it may be of interest to give the reader some notion of the relative frequency of the Diseases of the Spinal Cord which we have been describing, as seen in the wards of a large London hospital. For the following statistics the writer is indebted to his former house-physicians—Dr Halstead, of Ramsgate, and Dr E. W. Goodall, now Medical Registrar—1880–1889.

Among 301 consecutive cases of diseases of the spinal cord there were 167 of *paraplegia*—105 men to 62 women.

These might be classified as follows, on the plan adopted in the chapter with that heading.

(*a*) Paraplegia due to intrinsic causes: 78 cases, 25 with symptoms of acute *myelitis* (probably in two or three cases hæmorrhage into the meninges or cord), and the remainder chronic cases with more or less marked characters of *spastic paraplegia*. Three of the latter were congenital cases in children.

(*b*) Paraplegia due to extrinsic causes: from compression by *caries* of the spine, 22 cases; from *cancer* of the spine, 3. Paraplegia due to *tumours* of the cord or meninges: 4 cases—tubercle of the cord, glioma of brain and cord, and two meningeal tumours.

(*c*) Eighteen cases of paraplegia were diagnosed as due to *syphilis*; 12 were *alcoholic*, probably not all of them due to peripheral neuritis, and 30 were classed as *hysterical* or *functional*. One of the latter, in a man under the writer's care, was a case of divers' paraplegia.

In each variety, except hysterical paraplegia, there were more male than female cases.

There were 39 cases of *atrophic paralysis*, 25 male and 14 female. Of these, 3 were due to chronic cervical meningitis, and were thus distinct from the rest; only 15 were cases of infantile paralysis, but more were treated in the out-patients' room; there were 2 of adult spinal atrophic paralysis, 11 of progressive muscular atrophy, 1 of bulbar palsy and 8 of pseudo-hypertrophic paralysis in children.

Lastly, there were 83 cases of tabes, including 2 of Friedreich's disease, of which 75 occurred in men; and 12 of Insular sclerosis—5 men and 7 women.

There were no cases recorded of Landry's paralysis, nor of hemi-paraplegia. Cases of lead palsy were numerous, but were not classified among other forms of paralysis, and many of them were treated as out-patients.

DISEASES OF THE BRAIN

CEREBRAL DISORDERS DUE TO LOCAL LESIONS OF THE ARTERIES

'Αποπληξίη ὅλου τοῦ σκηνεὼς [*i. e.* σώματος] καὶ τῆς αἰσθήσιός τε καὶ γνώμης καὶ κινήσιός ἐστι παράλυσις. Ἦν δὲ κατάρχῃ κεφαλή, ἐπὶ μὲν τοῖσι δεξιοῖσι τὰ λάια παραλύεται δεξιὰ δὲ ἐπ' ἀριστεροῖσι.—ARETÆUS, A.D. 70.

"Paralyticos plerumque altero latere captos spectamus. Hæc hemiplegia vocatur. Fertur, et sane plurimorum jam medicorum observationibus confirmatur, latus adversum ab eo in quo cerebri vitium est, sic resolvi."—GREGORY'S *Conspectus*, 1832.

Anatomical effects of Obstruction of the cerebral arteries by embolism, thrombosis, syphilis, red and white softening—Effects of Hæmorrhage—Renal disease, atheroma, miliary aneurysms, as causes of cerebral hæmorrhage.
HEMIPLEGIA—*Its characters and extent—The local lesion—Course and sequelæ.*
APHASIA—*Amnesia—Agraphia—Their characters, seat, and physiology.*
APOPLEXY—*Symptoms, onset, and course—Determination of locality—Its diagnosis from injury, narcotic poison, alcoholic intoxication, pyæmia, uræmia, epilepsy—Diagnosis of the anatomical causes of apoplexy.*
Treatment of apoplexy and hemiplegia.

THE brain differs from the spinal cord in two particulars, which have an important influence on its pathology. Its lateral halves, instead of being closely united, are separated from one another, and expanded each into an independent mass. Its arteries, beside the minute twigs which run in from the pia mater to supply the cortex, are large trunks with well-defined areas of distribution. Consequently an important group of cerebral affections depend directly upon disease of the arteries of the brain, and their rupture or occlusion; and in these affections the symptoms are in a marked degree unilateral; any paralysis, or spasm, or loss of sensation in the body or limbs, is confined to one side or the other.

The result is either *Hemiplegia*, or loss of power in one arm and the corresponding leg; or the lesion is so severe as to interfere with both sides of the brain—a condition which has long been known as *Apoplexy*. Thus the affections in question contrast broadly in their features with those of the cord, which, as we have seen, are usually attended with a paraplegic form of paralysis, and are commonly slow in endangering life.

The boundary line is not fixed at the foramen magnum, for the medulla oblongata—which the physiologist recognises as the continuation upwards of the medulla spinalis—is subject to at least one of the diseases of the cord, that already described as bulbar paralysis. The pons may be the seat of lesions which are due to changes in its arteries, and cause a fatal form of apoplexy. In fact, both the bulb and the pons are liable at once to the special affec-

tions of the cord, and also to lesions of their blood-vessels, exactly like those of the higher cerebral centres.

To avoid the necessity of going over the same ground more than once, we will first give an account of the several diseases of the cerebral blood-vessels, of their respective causes, and of their anatomical effects; then we will proceed to discuss the symptoms to which they may give rise; and finally we will endeavour to show how we can diagnose these lesions from one another, and from affections of a different nature.

The vascular lesions in question fall into two groups: (1) those in which there is an arrest of the flow of blood through one or more of the cerebral arteries; and (2) those in which an artery is ruptured, allowing the blood to escape into the brain or beneath its membranes. The former group includes chiefly *embolism*, *thrombosis*, and softening from *syphilitic disease* of the cerebral arteries; the latter the various forms of *cerebral hæmorrhage*.

Obstruction of the cerebral arteries.—This may occur in various ways, which require to be separately considered.

(1) The obstruction may arise *outside the cranial cavity*. An example of this unusual event was Sir William Gull's case, in which arteritis deformans of the arch of the aorta led to complete obliteration of the innominate and left carotid arteries, so that the left subclavian artery alone was left to carry on the circulation in the brain. The patient, a woman aged forty-one, died paralysed and insensible; and certain parts of the cerebral centres were found to be in a state of softening. Some years ago a woman affected with carotid aneurysm was admitted into Guy's Hospital, who had nearly a year before been attacked with hemiplegia and loss of speech. Mr Durham performed the operation of ligaturing the common carotid artery, whereupon she regained to some extent the power of speaking. However, she died soon afterwards, and it was found that the aneurysmal sac extended upwards by the side of the internal carotid artery, and so pressed upon it that until the tension was lowered by ligature of the vessel below, the blood which reached the internal carotid from collateral sources had been unable to pass on to the brain. Much more commonly it is *after* ligature or compression of the carotid artery that hemiplegia sets in. Five or six cases of this kind have occurred at Guy's Hospital within recent years. In most of them the paralysis was the direct result of the operation; but in one instance it did not occur until three days afterwards, when the patient became suddenly hemiplegic while the dressings were being changed. It is possible that in those cases in which cerebral symptoms manifest themselves under such circumstances the communicating arteries which make up the circle of Willis may be abnormally small.

(2) *Embolism.*—In the immense majority of cases the cause of arrested circulation in the cerebral arteries lies within the skull; and it is generally an embolus—a clot derived from some distant source, and washed into the vessel by the blood-stream. Most frequently the starting-point of the morbid process is in vegetations on either the mitral or the aortic valves, the result of simple or ulcerative endocarditis. At an autopsy made in 1877 a rough friable mass of calcareous deposit was exposed upon the surface of the mitral valve, and a fragment of the same material was found wedged in one of the Sylvian arteries.

Sometimes stenosis of the mitral orifice is present, without roughness of its surface; the clot is in such cases almost always derived from

the dilated left auricle, where thrombi form in the recesses between the fleshy columns of its appendix; occasionally the formation of *ante-mortem* coagula in the chambers left of the heart may be independent of any valvular affection. In yet more rare instances the primary lesion is in the aorta itself. We have had at Guy's Hospital two such cases: in one there was a patch of softening thrombus which adhered to a diseased part of the wall of the great artery; in the other ulceration existed.

In the records of inspections during twenty-three years, there were forty-seven cases in which there was reason to believe that embolism of one of the cerebral arteries had occurred. It is true that in a very large number of them (twenty-one) no clot was discovered in any of the vessels at the autopsy, the interpretation of the cerebral symptoms as due to this cause being based upon their occurrence in persons who had disease of the cardiac valves, and upon the presence of such changes in the brain as are known to result from embolism. All writers admit that anatomical proof of plugging of the arteries is wanting in some fatal cases, especially when life has been prolonged for a considerable period. They suppose that the clot has in the meantime undergone absorption. That this may be the case is likely enough, but another possible explanation is that the spot at which the embolism was impacted may have been one of the bends of the carotid artery within the petrous bone or in the cavernous sinus, or where the vertebral artery winds round the arch of the atlas—parts which generally escape examination.

The vessel into which the clot passes is almost always one of the Sylvian arteries. In twenty-three cases embolism of these vessels was found at the autopsy, as against three cases in which its seat was the vertebral artery. The fact that embola entering the carotid are almost always carried into the Sylvian branch is doubtless owing to its course being more in a line with the trunk than that of the two other branches. Writers have stated that the left Sylvian artery is much more apt to be plugged than the right one, and an explanation for this supposed fact has been found in the difference of the angles at which the innominate artery and the left carotid artery respectively leave the aorta. But this statement is not confirmed by our experience at Guy's Hospital, for among twenty-one cases of embolism limited to the Sylvian artery of one side there were eleven in which the left one was affected, and ten in which the clot entered the right artery, a difference too slight to be noticed. The error (if error it be) has arisen from the statistical collection of miscellaneous cases from Journals and Transactions; the interest attaching to aphasia—a frequent result of embolism on the left side—must have often led to the publication of cases in which that symptom was present, while many of those in which it did not occur have been left unrecorded.

Our records do not bear out another statement often made—that cerebral embolism is most frequent in very young adults; for 12 cases occurred between the ages of thirty-one and forty years, as compared with 10 between twenty-one and thirty, 9 between forty-one and fifty, 8 between fifty-one and sixty, 6 between eleven and twenty, and 1 above the age of sixty. A slight preponderance of cases in male over those in female patients was probably accidental.

(3) *Thrombosis* of the cerebral arteries—the formation of clots *in situ*, independently of any extraneous source—is far less frequent than embolism. It is generally secondary to disease of the arterial wall, either atheroma, or

thickening with calcification. Occasionally it may perhaps be a direct result of feebleness of the heart's action. Nothnagel believes that the vertebral arteries are more liable to be affected by thrombosis than the carotids; and this accords with our experience at Guy's Hospital, where, against three or four cases of thrombosis of the basilar artery or of the posterior cerebrals, there was only one of a similar affection limited to the middle or anterior cerebrals. In one remarkable instance, both the carotid arteries, the middle cerebrals, the anterior cerebrals, and (it is said) the posterior cerebellar arteries were all obstructed by adherent clots. The patient was a man of thirty-five; and the other cases occurred in persons aged thirty, thirty-five, forty-eight, and forty-nine respectively. It would therefore appear doubtful whether thrombosis usually occurs at a more advanced period of life than embolism.

(4) *Syphilitic disease* of the cerebral arteries is one of the most important effects of the *lues venerea*. The first monograph devoted to it was written by Heubner, of Leipzig, and appeared in 1874. He assigns to a Danish writer, Steinburg, the credit of having first attributed to an affection of the blood-vessels many of the cerebral symptoms which arise as a result of syphilitic infection; and to Wilks that of having asserted that the change in the arterial coats is one of a special kind, different from the ordinary atheroma with which it had been confounded.

Heubner finds that the process begins between the endothelium and the fenestrated membrane. Here a number of cells accumulate, which form a mass that encroaches on the calibre of the vessel. In one instance the fenestrated membrane was in part destroyed, the growth penetrating into the muscular coat. He speaks of this as exceptional; but we have had two cases at Guy's Hospital in which what seemed evidently syphilitic ulceration of the vertebral artery passed right through the walls of the vessel into the substance of the pons Varolii. Heubner points out that with the arterial affection there are often associated gummata in the loose tissue of the pia mater at the base of the brain. The cells in the intima of the artery undergo development; the inner run into spindle-cells arranged transversely, the outer into interlacing stellate cells. The new tissue becomes vascular, and this perhaps saves it from undergoing retrograde changes. At any rate, it has hitherto been constantly found greyish white and semi-translucent, so that Heubner confirms the statement, which was originally made by Dr Allbutt, that it does not show the tendency to caseate which marks syphilitic affections of other parts. This may partly depend upon the fact that syphilitic disease of the cerebral arteries has hitherto been observed only in the large vessels at the base of the brain; one can hardly doubt that it must also occur in the smaller branches, where its effects would be less serious, so that it would be less likely to be seen in an early stage. As the channel of the artery becomes narrowed, the blood often coagulates in its interior, and thus the circulation through it is arrested. Although the process is known as *endarteritis obliterans*, Heubner doubts whether the growth by itself ever leads to complete obliteration independently of thrombosis. Ultimately a process of cicatrisation may take place, the cells developing into connective tissue, and the vessel undergoing conversion into a fibrous cord.

When a single vessel has been affected with syphilitic disease it has much more frequently been the carotid artery, or one of its branches, than the basilar, the proportion given by Heubner being as twelve to one. In

one of his cases the circulation at the base was interrupted at four distinct points; the left vertebral artery was obliterated, and so were also the basilar, the left middle cerebral, and the origin of the right anterior cerebral arteries. In most instances several arteries become diseased simultaneously, but syphilitic endarteritis is not diffused so widely as atheroma, and it tends to narrow and occlude the affected arteries rather than to dilate and render them tortuous. Moreover, it affects smaller arteries.

It is generally at an advanced stage of syphilis that the cerebral arteries become affected. Among the cases collected by Heubner the oldest patient was fifty-one years old, the youngest twenty-two; and the numbers were pretty evenly distributed over the three decennial periods between twenty and fifty years of age.

All Dr Gowers' fifty cases occurred between the ages of twenty-one and forty-five, and there were three in men to one in women. The Sylvian branch of the internal carotid artery was affected in nineteen out of twenty cases.

Syphilitic disease of the arteries of the brain, like every other remote effect of syphilis, occurs in persons who are ignorant of having the disease, and who are free from eruptions, nodes, and its other obvious signs. At Guy's Hospital, since the first case recorded by Wilks in 1863, we have had numerous well-marked instances of the affection, besides others of a more doubtful character; but except in a few with a history of syphilis, the proof of their origin depended upon the presence of gummata in the liver or testes, or of lardaceous disease.

Effects of obstruction of cerebral arteries.—The histological state of the brain, when there has been arrest of the circulation in one or more of the arteries, nearly corresponds with what might have been expected from the effects of interference with the arterial blood supply to other tissues. In general it may be said that the affected parts are *softened;* indeed, the various affections now under discussion include the majority of those cases which by the pathologists of the last generation were classified as "softening of the brain."

The anatomical relations of the vessel which happens to be obstructed of course determine the regional distribution and extent of the morbid change; and upon this, in turn, depends the nature of the symptoms. With regard to the Sylvian artery, we shall find that the whole clinical aspect of a case differs according as this vessel is plugged at its origin, or a little further on in its course.

Thus it is of great importance to the physician to be acquainted with certain investigations as to the exact mode of distribution of the cerebral arteries, which have been worked out by two independent observers, Duret in France, and Heubner in Germany. As they point out, the small arteries that alone enter the tissue of the brain form two separate systems, which may be distinguished as that of the cortex and that of the central ganglia (the corpus striatum and thalamus) respectively. These systems are altogether independent, and no anastomoses take place between them; the zone at which they meet within the cerebral substance is situated about an inch and a half beneath the convolutions. The "central" arteries arise directly from the trunks forming the circle of Willis; they are entirely unprovided with anastomoses among themselves. The "cortical" arteries spring from a network in the pia mater, in which tolerably free communications exist between the tertiary branches of the same trunk, and even (in some individuals) between the branches of different trunks.

Let us now apply these facts to explain the effects of obstruction of the

Sylvian artery at different points. That artery, close to its origin, gives off a number of small "central" twigs, which supply the whole corpus striatum (except the inner end of the caudate nucleus), and also the anterior part of the thalamus. It then divides into four terminal branches, of which one is distributed to the third frontal convolution, while the other three pass to the second frontal, the two "central" ascending frontal and ascending parietal, the three convolutions of the parietal lobe, and the three temporal convolutions.

When the middle cerebral artery is obliterated beyond the point at which its "central" offshoots arise, the superficial parts of the brain are the only ones to suffer. And since the subdivisions of the vessel in the pia mater anastomose with those of the anterior and posterior arteries, it is not certain that in the supposed case any softening will result. There may be merely a temporary interference with the circulation in the area to which the Sylvian branches are distributed; or a limited part in the midst of this area may be permanently deprived of its blood supply; or, lastly, almost the whole of the convolutions enumerated above may undergo destruction. Thus Charcot has recorded an instance in which an enormous superficial patch of softening involved the ascending frontal and the ascending parietal convolutions, as well as those of the insula, the corpus striatum and thalamus remaining intact. The differences in the result in different individuals depend partly upon variations in the extent to which the vessels communicate with one another, partly upon whether the plugging takes place suddenly or gradually. It is, of course, quite possible for a single one of the four terminal branches, such as that to the third frontal convolution, to undergo obstruction apart from the rest.

On the other hand, when the seat of the lesion is at the spot where the Sylvian artery arises from the internal carotid, the basal ganglia suffer; and in their case softening is almost inevitable, because their arteries have no anastomoses: it is only when the closure of the vessel takes place very slowly, as the result of chronic disease of its coats, that collateral channels sometimes seem to develop themselves, so that the blood supply is maintained. When the main channel of the Sylvian artery has been obliterated, extensive morbid changes in the corpus striatum and thalamus are likely to occur, while the convolutions may entirely escape.

Local effects of obstruction.—The appearances presented by the affected parts of the brain vary considerably under different conditions. When the patient dies rapidly the cerebral substance may look perfectly healthy. This was found to be the case in an autopsy on a man who was attacked with hemiplegia twenty-six hours after ligature of the internal carotid artery, and who lived only fifty-seven hours afterwards. Where closure of an artery takes place gradually, the regions of the brain that are deprived of their normal blood supply often fail to suffer as much as might be expected. Heubner remarks that in syphilitic affections of the cerebral arteries the nutrition of the cortex is seldom seriously interfered with, unless two adjacent trunks out of the six that arise from the circle of Willis are completely obstructed. In the case already referred to, in which the circulation at the base of the brain was interrupted at four distinct points, there was no softening at all, although one Sylvian artery was obliterated.

When arrest of the flow of blood through a cerebral artery takes place gradually—as in thrombosis and in syphilitic disease—the morbid changes in the brain, if any, take the form of *softening*. The affected parts are

sometimes diffluent, being replaced by a milky liquid, which occupies an ill-defined cavity, containing some loose shreds of connective tissue, and perhaps roofed in by the pia mater or by the ependyma of the lateral ventricle. Every intermediate degree of consistence may occur up to a point at which one can hardly perceive any difference from the healthy substance around, until one allows a gentle stream of water to play over the diseased surface, when it soon becomes ragged and assumes a worm-eaten appearance.

The colour of softened parts of the brain is very variable; it may be white, or yellow, or brownish. Writers have been accustomed to describe separate varieties of the affection according to colour. But (except "red softening," which will be described hereafter) such distinctions have no real existence, and have led to great confusion. As a matter of fact, the condition now under discussion is that which most English pathologists call "white softening," but by Rindfleisch it is named "yellow softening;" and each of these two epithets is susceptible of an entirely different application; for the German writer uses the term "white softening" for a morbid appearance in the central parts of the brain in cases of hydrocephalus, and in England we have been accustomed to describe as "yellow softening" the œdematous state of the cerebral substance that is so often found in the neighbourhood of tumours.

The differences in colour in different cases of softening of the brain depend on the presence of more or less extravasated blood, or on its entire absence. The blood undergoes disintegration with the tissue-elements among which it lies, and under the microscope it is easily recognised in the form of yellow or red granules, or of hæmatoidin crystals. The microscope also reveals in softened brain-substance "compound granule-masses," or "corpuscles of Gluge," often in large numbers. These mulberry-like aggregations of minute granules of oil have already been mentioned as occurring in softening of the spinal cord, and indeed they are found in many degenerating tissues. They are probably degenerated exudation-cells.*

In cases of *embolism*, softening is, as a rule, the only change presented by the parts of the brain deprived of their blood supply. Sometimes, however, there is reflux hæmorrhage from the veins, as occurs in the lungs and spleen. After ligature of the carotid artery the corresponding cerebral hemisphere is now and then found in a condition of vascular turgescence, precisely like the early stage of an infarctus. Thus in an autopsy made by Dr Wilks, all the vessels on the affected side of the brain—including the veins as far as the longitudinal sinus—were distended and filled with coagula, and the substance of the organ, which was pulpy, was of a dark red colour. So, again, in those cases of embolism that have occurred at Guy's Hospital, a condition of "red softening" is described as having been present, and in two other cases tough yellow masses were found which exactly resembled the wedge-shaped patches that are so common in the spleen and the kidney.

"Red softening" is a change of doubtful significance. It may be softening as above described in which a multitude of minute extravasations of blood have taken place; or it may be an early stage of "white" or "yellow softening"—the reason for its not being seen in cases of thrombosis

* Huguénin admits no less than seven origins of these corpuscles—the nuclei of the neuroglia, the cells which make up the walls of the capillaries, those of the "adventitia" of the arteries, the nuclei of the smooth muscular fibres of the vessels, those of the perivascular lymph-spaces, the spindle-cells of the cortex, and very probably its ganglion-cells.

or syphilitic endarteritis being that in these cases death does not take place soon enough; or it may be a true local *inflammation*, to be described in a future chapter.

Again, the coats of the artery itself often become softened, and yield immediately below the seat of obstruction, so that an *aneurysm* is formed. Repeated examples of this have been observed at Guy's Hospital within the last few years; in one of them Dr Goodhart found an aneurysm on the Sylvian artery on each side. It was not indeed proved in every instance that plugging had occurred, but all the patients had disease of the cardiac valves, and in other cases the anatomical evidence of embolism sometimes fails us. Death was in most cases due to rupture of the aneurysm, blood being extravasated in considerable quantity into the pia mater, the corpus striatum, or the lateral ventricle. But, in addition, cerebral hæmorrhage has been the cause of death of seven other persons who were affected with ulcerative endocarditis or had vegetations on their mitral or aortic valves; in all probability an aneurysm, itself the result of embolism, was present in these cases likewise, although it escaped notice at the autopsy.

Sir William Gull long ago taught that it was chiefly in young subjects that intra-cranial aneurysm should be suspected as a cause of cerebral hæmorrhage; and Dr Church, in tabulating a series of cases of this kind, confined his attention to individuals under twenty years of age. But of nine cases which occurred at Guy's Hospital, while seven were between fourteen and twenty-six, one patient was thirty-four and another fifty years old. We have already seen that embolism is by no means so strictly limited to an early period of life as has been generally supposed.

Cerebral hæmorrhage.—Although effusion of blood into the brain may be the result of embolism, of purpura, or of mechanical injury, yet in the great majority of cases it is due to primary disease of the cerebral arteries and their consequent rupture.

Since the days of Morgagni it has been known that hæmorrhage is far more apt to occur in or near one of the corpora striata than in any other part of the brain. But certain anatomical facts have been made out by Gendrin and other observers which have not only led to a more exact determination of its seat, but have also gone far towards explaining why this spot should be so generally the seat of rupture of an artery. Outside each lenticular nucleus there is a mass of white substance called the "external capsule." In recent brains the two structures seem to be continuous; but after a brain has been hardened in spirit it is found that they can be separated from one another with great ease, and apparently, although not really, without any nervous fibres being torn through. Thus the connection between them must be somewhat imperfect. Now, the central branches of the Sylvian artery, which supply the corpus striatum, run upwards for some distance outside the lenticular nucleus before penetrating into its interior. These are more liable to laceration than those of the hemispheres generally, because they are less supported. Moreover, they are much larger than the nutrient arteries of the cortex, they have no anastomosis with one another, and they arise directly from a large trunk, which may almost be said to come in a straight line from the heart. Indeed, as Watson long ago noticed, when injections are forced into the cerebral arteries of the dead body it is in the corpora striata that the vessels are most apt to give way, and the material injected to be extravasated. Charcot calls one particularly large lenticulo-

striate branch "the artery of cerebral hæmorrhage." It is true that the rupture of any artery in the brain is always preceded by the occurrence of morbid changes in its walls; but while this diseased state is common to most of the cerebral vessels, the special liability to rupture of those in the external capsule may be explained by the considerations just offered.

The blood begins by making for itself a space between the lenticulus and the external capsule. At first it forms a thin layer, but as it increases in quantity it gradually becomes a rounded mass. It now flattens out the claustrum and the island of Reil, which lie below and to its outer side; it pushes inwards the corpus striatum, and also the thalamus if it extends far enough backwards. When it accumulates slowly it may press upon the parts around, so as to form a smooth-walled cavity for its reception. But more frequently it tears up irregularly the white matter of the hemisphere and the outer part of the lenticulus. In some rare cases it reaches the superficial convolutions; far more often it ruptures into the lateral ventricle. Coagulation quickly occurs, and at an autopsy we may find a mass of clot weighing four ounces or more. Within the lateral ventricles there is sometimes a red liquid, consisting of blood mixed with the cerebro-spinal fluid; sometimes a clot occupies one ventricle, while the contents of the other are only bloodstained, with perhaps a little clot in the cornua. Dr Broadbent has noticed that the middle ventricular cornu, close to the seat of the hæmorrhage, is commonly empty, having been compressed by the extravasated blood before rupture into the cavity of the ventricle took place. Not infrequently the third ventricle, the aqueduct, and the fourth ventricle are all filled with moulded coagula exactly fitting their cavities; the blood may even escape along the subarachnoid space so as to reach the exterior of the bulb and of the pons, and the parts at the base as far as the opposite Sylvian fissure. The fissure on the side of the hæmorrhage is too closely compressed to receive any of the blood. Indeed, the convolutions of the vertex of that hemisphere are often greatly flattened, so that as soon as the skull-cap is taken off one sees at once which side is affected.

Seat of hæmorrhage.—Of 95 consecutive fatal cases of cerebral hæmorrhage that have occurred at Guy's Hospital—

In 70 the seat of the lesion was in or near the *basal ganglia*. In only 4 of these cases is it stated that the blood was confined to the substance of the hemisphere, not having found its way either to the surface or into the ventricles. In 57 it is expressly recorded that laceration into the lateral ventricle had taken place; and in 22 of these the fourth ventricle also contained either a clot or bloodstained fluid. In 6 cases the superficial convolutions were reached. In 6 instances the part into which the blood was effused was behind the thalamus, somewhat beyond the limits of the region which is the usual seat of cerebral hæmorrhage. Twice the caudate nucleus was alone affected. The right side of the brain was attacked in 36 of the 70 cases, the left side in 34.

In 12 of the remaining 25 cases the seat of the hæmorrhage was in the *pons Varolii;* in 1 it was in the right half of the *cerebellum*. Among the cases of "apoplexy of the pons" there were 5 in which the blood had escaped into the fourth ventricle; and 2 in which it had oozed out through the convex surface of the pons, so as to reach the base of the brain. In no less than 8 of the cases in which there was hæmorrhage in the neighbourhood of the corpus striatum, blood was also effused into the pons; in one instance three independent hæmorrhages were found in this part.

Lastly, there were 12 cases in which the extravasation was into the *membranes* on the surface of the brain. "Meningeal apoplexy" is often described as a distinct affection; and this is justified by the fact that it is sometimes connected with blood poisoning, purpura, anæmia, or pneumonia, and is sometimes caused by blows or falls on the head. But in the twelve cases here cited it was associated with exactly the same changes in the heart and kidneys which we shall see to be commonly found with ordinary cerebral hæmorrhage, and there is every reason to believe that the difference in seat was accidental. The quantity of blood was often large; the nerves at the base of the brain were buried in a thick clot, and the extravasation extended along the Sylvian fissures and in the meshes of the pia mater over the surface of the hemispheres, and also in some instances along the subarachnoid space to the spine, and into the fourth ventricle.

Among 912 cases of non-traumatic intra-cranial hæmorrhage, collected from various sources, the writer found that nearly 65 per cent. were in the *cerebrum*, and more than five sixths of these in the corpus striatum, thalamus, or adjacent parts; that more than 20 per cent. were *meningeal*, nearly 10 per cent. in the *pons*, and about 5 per cent in the *cerebellum*—a proportion not widely different from that observed in the above ninety-five cases collected for the first edition of this book.

Histological effects of hæmorrhage.—When life has been prolonged for a few days after the occurrence of cerebral hæmorrhage, the brain tissue round the clot commonly exhibits reactive changes. At first it is reddened, or visibly ecchymosed; then it becomes œdematous and of a yellow colour, exactly as occurs around a tumour of the brain. At a still later period it may be found in a state of softening. Whether suppuration ever takes place round a clot, as was previously supposed, is very doubtful. Sir Thomas Watson relates a case for which he adopted this explanation; but it is not unlikely that the clot, which was found lying in an abscess, was really of later date than the pus.

But often cerebral hæmorrhage does not destroy life, so that there are other morbid appearances, besides those that are seen in cases which prove directly fatal. In the records of *post-mortem* examinations at Guy's Hospital the author found twenty-one cases in which the remains of effusions of blood of old date were discovered in one of the central ganglia or in their immediate neighbourhood. And ten of the seventy-one cases of recent cerebral hæmorrhage presented additional patches of earlier origin. Sometimes all that was left was a soft tawny discoloured spot, containing abundant granule masses and crystals of hæmatoidin; or a tough, flat, fibrous mass, an "apoplectic cicatrix." Sometimes there was a well-defined membranous cyst, with shreds of connective tissue and a clear or turbid fluid in its interior. In one instance the cavity was of the size of a walnut; in another it was as large as a bantam's egg. Such appearances have been plainly recognised thirteen or fourteen years after the attack, when the patient has died of some different disease. None of our cases enabled us to say within how short a time it is possible for a clot in the brain to undergo absorption and for a cyst to take its place. It may be worth while to notice, that in no single instance in which the remains of an apoplectic clot have been found in the brain after recovery, has there been any indication that the blood had made its way into the lateral ventricle. But according to the statements of Rokitansky and Charcot it would seem that in some very rare cases even effusion into the ventricle is not inevitably fatal.

Ætiology.—With regard to the causes of cerebral hæmorrhage considerable differences of opinion still prevail. In this country the most obvious pathological change found in the bodies of those who have died of effusion of blood into the brain is undoubtedly *chronic renal disease.* Among 116 cases* which came under observation consecutively in the dead-house of Guy's Hospital some morbid condition of the kidneys is stated to have been present in eighty-six; while in only fifteen out of the whole number is it reported that these organs were healthy. But, strange to say, Continental pathologists seem not to have found the kidneys diseased in a similar proportion of cases. Charcot and Bouchard say that interstitial or parenchymatous nephritis was present in only three among forty-nine cases of theirs in which it was looked for, there being, however, thirteen other cases in which the kidneys were "simply atrophied." Nothnagel, in 'Ziemssen's Cyclopædia,' appears to be equally ignorant of the close connection between renal affections and cerebral hæmorrhage, for he quotes, almost without comment, the statement of Frerichs that among 241 cases of Bright's disease there were only six in which effusion of blood into the brain occurred. This, indeed, is not so incompatible with the English observations as might at first sight appear. For none of our cases have been examples of the tubular (epithelial, parenchymatous, or catarrhal) form of Bright's disease; and comparatively few of them seem to have presented those conditions of mixed epithelial and interstitial changes which are so commonly the cause of dropsy and other symptoms in persons at the middle period of life. In the great majority the renal affection has been of the "granular" kind, the organs having shrivelled up into mere relics of their former structure, but retaining their red colour unaltered. In a few instances one kidney had undergone destruction from calculous affection of its pelvis, or the two organs had each become converted into a large tumour made up of a congeries of cysts. It is possible that in such cases the occurrence of cerebral hæmorrhage was merely an accidental coincidence.

All trustworthy observers are agreed that morbid changes in the arterial walls precede their rupture, but when the cerebral arteries are already diseased, there can be little doubt that the hypertrophied left ventricle and high tension of chronic Bright's disease make hæmorrhage more likely, just as we shall see that it not infrequently follows a sudden and temporary increase of blood-pressure.

Sometimes the arteries which arise from the circle of Willis are found to be extremely *atheromatous*, or their walls are extensively calcified.

In the case of a man aged forty, who died in Guy's Hospital in 1869, and who had a hypertrophied heart and granular kidneys, there was a small *aneurysm* on the left middle cerebral artery which had given way and poured blood into the Sylvian fissure, while there was also a large clot outside the corpus striatum, with laceration into the lateral ventricle, apparently of independent origin.

In 1866 Bouchard discovered, in a case of cerebral hæmorrhage from the wards of M. Charcot, two small aneurysms upon one of the vessels; and since that time these two French observers have published seventy-seven cases of the same kind, in every one of which they demonstrated the presence of what they term *miliary aneurysms.* These are described as minute

* All those instances were excluded in which there was reason to believe that embolism was the starting-point of the lesion, and also a few cases of meningeal hæmorrhage, which accompanied purpura, or were due to an injury.

globular or fusiform swellings, from one fifth of a millimètre to one millimètre ($\frac{1}{125}$ to $\frac{1}{25}$ of an inch) in diameter, so as to be plainly visible to the naked eye. They are sometimes very soft, sometimes firm and elastic, sometimes hard like grains of sand. In colour they are purple, or reddish brown, or greyish, according to the thickness of their walls, and the state of their contents, which may be either fluid blood or more or less decolourised clot. They are generally multiple, but sometimes only two or three can be discovered in the whole of the brain after careful search; sometimes as many as a hundred have been counted. They are most conspicuous upon the surface of the convolutions and in the sulci between them; their favourite seat is the deep layer of the grey matter or the line of junction between it and the white. But they may also be found in the thalami and corpora striata, in the pons, and elsewhere. MM. Charcot and Bouchard admit that, when an extensive effusion of blood into the brain has occurred, it is difficult to find the miliary aneurysm the rupture of which they suppose to have led to the hæmorrhage. The best way is to place the affected hemisphere in a basin, and to change the water frequently by tilting, without skaking it. After a time the clots become loosened and float away, leaving a number of little bloody masses connected by vascular filaments with the brain-tissue beneath. Most of these, when magnified, show only the open ends of vessels, torn across secondarily by the extravasated blood, and covered with little caps of fibrin that require to be carefully distinguished from actual aneurysms; but at length some are found which contain spherical ampullæ, continuous with small arteries and split on one side.

It is evident that the discovery of MM. Charcot and Bouchard affords only a partial explanation of the pathology of cerebral hæmorrhage, since miliary aneurysms are not found with especial frequency in that region of the brain which we have seen to be so generally the seat of effusions of blood. Indeed, the French observers themselves point out that the lesion which they describe is, after all, but one of the effects of a diffused morbid change in the cerebral arteries—a chronic "sclerous periarteritis,"—consisting in thickening of the arterial sheath and of the adventitia, with overgrowth of nuclei, while the muscular coat undergoes atrophy. At first they supposed that this condition was peculiar to the vessels of the brain; but another observer at the Salpêtrière, M. Liouville, has since demonstrated the occurrence of a similar affection in the arteries of other parts, and even speaks of having found miliary aneurysms beneath the mucous membrane of the œsophagus and upon the surface of the heart. We are brought by these investigations on sclerous periarteritis to almost precisely the same point to which we are led by the observations of Sir William Gull and Dr Sutton on "arterio-capillary fibrosis." Indeed, it seems clear that the French and the English pathologists have been studying the same morbid process, and their general agreement confirms the accuracy of their conclusions. It is strange, however, that MM. Charcot and Bouchard failed to notice the affection of the kidneys.

There can be little doubt that this diffused change in the arteries of the brain is often the cause of impairment of the nutrition of the brain, attended with such obvious softening of its substance, as must increase the risk of arterial rupture. Charcot and Bouchard quote Rochoux as having first taught the doctrine of *ramollissement hémorrhagipare*, which was further developed by Todd; but they maintain that the only "softening" that bears any rela-

tion to cerebral hæmorrhage is the secondary affection which we have seen to be of frequent occurrence in the tissue round a clot. In the records of *post-mortem* examinations at Guy's Hospital, however, there were no fewer than twenty cases in which localised patches of white softening were found in different parts of the brain—sometimes in the corpora striata or thalami, sometimes in the pons, sometimes in the hemispheres. Many of the patients had suffered from gout; a large majority had granular kidneys and hypertrophied heart; and there is not a single instance in which the kidneys are said to have been healthy. In the ages at which they prove fatal, and in the circumstance that the large majority of the patients were males, these cases corresponded exactly with those of cerebral hæmorrhage; and probably it was a mere accident that death occurred before any of the arteries in the softened patches gave way.

Sex and age.—Cerebral hæmorrhage does not occur with equal frequency in the two sexes or at different periods of life. Men are much more liable to it than women. Of 113 consecutive fatal cases at Guy's Hospital, 82 occurred in men, and only 31 in women.

Among 110 of these cases, in the reports of which the ages of the patients are stated, there were 6 between twenty-one and thirty, 18 between thirty-one and forty, 37 between forty-one and fifty, 29 between fifty-one and sixty, 17 between sixty-one and seventy, and 3 above the age of seventy. These figures do not altogether correspond with the statements of writers in general, who make the frequency of apoplexy increase up to the age of seventy or even eighty years, not only relatively to the numbers of persons living at different ages, but also absolutely.* It may be that men at a middle period of life are more likely than those who are older to be brought to the hospital when attacked with apoplexy, because their relatives are not so apt to suppose that the case is hopeless.

Whether cerebral hæmorrhage is particularly common in men with short thick necks and florid faces is doubtful; but there can be no question that gout is indirectly a cause, by setting up granular disease of the kidneys.†

Cerebral hæmorrhage sometimes occurs first while the patient is making some violent effort, or subjecting his vascular system to an excess of pressure, so that one can hardly help regarding this as the exciting cause of the attack. Thus two of our patients had been running to catch a train; another was a woman who had recently suffered from sea-sickness in crossing from France. All writers mention sudden emotions, violent efforts, cold baths, straining at stool, prolonged laughing, coughing, or sneezing, indulging in stimulants, as capable of bringing on the rupture of an artery in the brain, provided that the vessel is in the diseased condition which seems to be a necessary antecedent of hæmorrhage. Among labouring men many are attacked while at work; but one must not forget that this takes up a great part of their daily lives, and cerebral hæmorrhage occurs in a large number of persons during sleep, when the pressure in the cerebral vessels is supposed to be particularly low. Intoxication seems to be a frequent immediate occasion of cerebral hæmorrhage. Sir Thomas Watson refers to two cases in which men were attacked by hemiplegia while in the act of sexual intercourse;

* Gintrac's 658 cases (excluding meningeal apoplexy), as quoted by Bastian, give for the corresponding ages: under 20, 6 per cent.; 21—30, 7 per cent.; 31—40, 11 per cent.; 41—50, 15 p. c.; 51—60, 20 p. c.; 61—70, 23 p. c.; and above 70, 19 p. c.

† Quæ (animæ) subito revelluntur e crasso corpore multum corporeæ molis secum ferunt: tales autem mittit apoplexia.—*Erasmi Colloquia: Charon.*

and a most severe case of apoplexy followed by hemiplegia occurred under these circumstances in a man fifty years of age, a patient of the writer, who remained hemiplegic for more than two years, and then died of a second attack.

The symptoms of obstruction and of rupture of the cerebral arteries differ in some points; but the three most important—*Hemiplegia*, *Aphasia*, and *Apoplexy*—are common to them all, and will now be separately considered. They are each of great pathological and clinical interest.

HEMIPLEGIA.—The division of the encephalon into two separate hemispheres, each with its own system of blood-vessels, makes unilateral lesions frequent, in striking contrast to the extreme rarity of hemiparaplegia.

Motor symptoms.—The limbs which are affected are always those on the side opposite to the lesion in the brain. This depends upon the fact that the motor columns cross over in the anterior pyramids; those which emerge from under the right half of the pons Varolii passing down into the left half of the spinal cord, and *vice versâ*. Thus any unilateral affection of the nervous centres, situated above the decussation of the pyramids, if it causes paralysis at all, affects the opposite side.*

It is remarkable that this fact was well known to the Greek physicians, who correctly explained it as due to the nerves crossing like the letter X, but was forgotten or doubted as late as the present century. Compare the quotations which are printed at the head of this chapter from Aretæus in the first century, and from Dr James Gregory, professor of medicine at Edinburgh, in the nineteenth.

Although hemiplegia means a stroke paralysing half the body, the extent to which it affects the muscles varies greatly. As a rule, in what may be called "common cerebral hemiplegia"—the *hémiplégie cérébrale vulgaire* of Charcot—the paralysis extends to the opposite arm and leg, the lower part of the face, and the tongue. In the most severe forms the muscles of the trunk are obviously weakened, in slighter attacks the tongue and face almost entirely escape, and in some the leg also is so little affected that the case might be mistaken for one of brachial monoplegia. Moreover, the hand is always more affected than the arm, and the arm than the shoulder, the foot than the hand, and the leg than the thigh. In the facial muscles, commonly all that is noticeable is a little loss of expression

* There are some cases on record which seem to be exceptions to this rule, and these were once marshalled forth by Dr Brown-Séquard, who believes that they establish the possibility of the occurrence of hemiplegia on the same side as the lesion on which it depends. But, whatever the absolute number of cases of this kind that can be collected from medical journals and other sources, it is altogether insignificant in comparison with that of cases on which the rule of decussation is based.

In some of the supposed exceptions it is most likely that the reporters have written "right" for "left," or "left" for "right." Everyone who has done much case-taking will admit how easy it is to fall into this error. Our records at Guy's Hospital contain at least two cases in which it is stated that the disease was on the same side as the paralysis; and one of these is in the hand-writing of Dr Wilks, who certainly must have been struck by such a fact, if he had observed it; but he leaves it entirely without comment, and there can be no doubt that it was a slip of the pen.

In other cases it is probable that there really were two lesions: one, the more conspicuous, on the same side as the hemiplegia; the other on the opposite side—perhaps a minute spot of softening—which really caused the paralysis, but was overlooked.

Another explanation, viz. that in some persons there is no crossing of the anterior pyramids, is unsatisfactory: first, because there is no evidence that the crossing is absent in the cases in question; and secondly, because in man and animals the crossing is of variable completeness, and when deficient is probably made up for by crossing lower down.

about the mouth, which may appear to be drawn over to the opposite side.* This was well shown in the case of Henry W—, admitted into Guy's Hospital on February 20th, 1860, under the care of Dr Gull, for right hemiplegia, which was almost complete. The state of his face was very interesting. When told to shut his eyes he could close them both. But whereas he could wink with the left eye alone, he could not do it with the right alone; and when he was asked to compress the eyelids firmly the left orbicularis palpebrarum alone obeyed the will, the right one merely bringing the upper and lower lids into contact, without any wrinkling of the skin. This, and the further observations which the author made on the same patient, led him to the conclusion that "those movements which are performed in harmony by the two sides of the face or body remain unimpaired in hemiplegia."

In 1866, in an article in the 'Medical and Chirurgical Review,' Dr Broadbent first laid down this law, and it has received general acceptance.†

The exemption of movements which are habitually bilateral (but not always necessarily performed by corresponding muscles of the two sides) is seen in the case of the muscles of the eyeballs, of the masticating muscles, and of those of the neck, chest, and abdomen, all of which retain their power.

Not infrequently the face escapes entirely. Sometimes the leg can be moved, while the arm is completely paralysed. Almost invariably, when recovery takes place, the patient regains power in the leg earlier than in the arm; he may perhaps be able to walk with a crutch at a time when he can scarcely move the fingers at all, and if any part remains permanently paralysed it is the upper limb. These facts may be explained by the movements of the arm being more independent than those of the leg, and furnish a further illustration of Broadbent's rule that the limb of which the movements are more highly specialised suffers most and longest.

Again, the highly differentiated movements of fingers are more affected than the coarser movements of the shoulder. The *tongue*, however, is often only partially paralysed; when it is protruded from the mouth its tip is more or less distinctly turned towards the side on which the limbs are paralysed, and the patient often articulates indistinctly and mumbles in his speech; so much that he may in some cases be unintelligible.

It was formerly considered difficult to understand why the hypoglossal nerve and the portio dura—arising as they do above the decussation of the anterior pyramids—should nevertheless resemble the nerves of the limbs in showing impairment of function on the side opposite the lesion in the brain. Physiologists are now agreed that this depends upon the fact that the fibres which pass to the roots of those nerves undergo an independent decussation within the substance of the medulla oblongata or pons.

Dr Broadbent's rule must not be taken to mean that there is never any loss of power whatever in muscles which are used in association with those of the opposite side. It has been proved by several independent observers that the chest sometimes does not expand fully on the paralysed side, at least when a deep breath is being taken. Dr Walshe ('Lancet,' 1849) determined this by actual measurement. Dr Broadbent himself points out that when a hemiplegic patient is made to raise himself from the recumbent

* Todd ascribed this to impaired power of the buccinator muscle (which he believed to be supplied by the fifth nerve), and maintained that the facial nerve escaped altogether.

† In 1860 or 1861 I read before the Physical Society of Guy's Hospital a paper in which I developed the same theory; of course, as I did not print it, the priority rests with Dr Broadbent.—C. H. F.

posture by his abdominal muscles alone, the rectus on the paralysed side can be felt to act somewhat less powerfully, and a little later than on the healthy side. So, also, if he is told to close the jaws firmly, the masseter and temporal muscles do not contract quite simultaneously or with equal force on the two sides.

It is remarkable that when there is profound paralysis of the face or arm, movements may still be called forth by emotional or involuntary stimuli, which the patient is quite unable to execute by his own efforts. Thus a hemiplegic may raise his shoulders in yawning, or contract his zygomatic muscles in laughter, when he cannot perform the same movements in the least by a voluntary exertion. We may associate these facts with the curious observation that a patient who is speechless from apoplexy sometimes makes a short exclamation when it is forced from him by some sudden emotion, and with the escape of the muscles of respiration and of organic life in hemiplegia. But it is hard to say where we are right in seeking an anatomical explanation, and where we ought to be content to regard them as examples of a physiological or evolutionary differentiation of function.

As Dr Jackson many years ago pointed out, patients suffering with aphasia, from disease situated above the corpus striatum on one side, are sometimes quite unable to protrude the tongue from between the teeth. We have several times observed this at Guy's Hospital, and at the present time there is an instance of it in Philip Ward (Jan., 1890). It seems clearly to be an instance of double paralysis from a unilateral lesion; but we may perhaps attribute it to an inhibitory influence transmitted downwards upon the associated nuclei of the ninth nerves in the pons, rather than believe that both sides are "represented" in each cerebral hemisphere. This is the hypothesis suggested by Dr Jackson to account for the supposed occurrence of paralysis of all the limbs as the result of an affection of one hemisphere ('Brit. Med. Journ.,' 1874).

In some cases of hemiplegia the eyes, instead of being directed straight forward, are turned to one side, and this side is always opposite to that of the paralysis, so that, for the purpose of artificial memory, one may say that the patient "is looking towards the lesion in his brain." This *conjugate deviation* of the eyes is by some writers regarded as due to a paresis of certain ocular muscles—the external rectus on the side of the paralysed arm and leg, the internal rectus on the other side. Others have supposed it to depend upon spasm of the antagonist muscles, and thus to be analogous to the state of "early rigidity" which will presently be described. But the face also is sometimes drawn over, away from the hemiplegic limbs, and in such cases Prévost found that the sterno-mastoid and the trapezius muscles are not necessarily in a state of contraction. Moreover, Dr Jackson has pointed out that when "early rigidity" comes on in the arm and the leg the "conjugate deviation" becomes reversed, the eyes being now directed towards the side of the paralysis; a case in point occurred at Guy's Hospital in 1867 in the practice of Dr Rees. Thus it seems clear that this remarkable symptom is not of a spasmodic nature, and Vulpian and Prévost are probably right in supposing that it represents, in a rudimentary form, the rotatory movement (*mouvement de manège*) which is so commonly developed in animals after unilateral injuries to the head. Indeed, a woman under the care of Charcot for left hemiplegia with conjugate deviation of the eyes was several times found lying across her bed with her head to the right and her feet to the left; and another of the patients whose cases are

related by Prévost showed a tendency to turn round like a top when placed upright. This writer has proved that the occurrence of conjugate deviation of the eyes is not limited to affections of any one region of the brain: among fifty-eight cases which he collected there were four of meningeal hæmorrhage, and four others in which the superficial convolutions were alone diseased. It is generally transitory, lasting only a few hours or a day or two; but sometimes it persists for several months.

We have seen that in common cerebral hemiplegia there is no complete paralysis of any of the cranial nerves, but in a less common group of cases palsy of the third or of the seventh nerve is associated with hemiplegia, and then the seat of the disease can be determined with more than usual exactness.

The *facial nerve* may be affected in two different ways. On the one hand, the lesion, if it is situated in the upper part of one lateral half of the pons, may destroy the facial nucleus, and so cause a total loss of power in the face on the same side on which the arm and the leg are paralysed; and since the nucleus of the sixth nerve is very close, paralysis of the external rectus may perhaps be present in addition. On the other hand, an affection of the lower part of the pons on one side may cut the fibres of the facial nerve as they are passing across the motor tract, after they have decussated on their way outwards from their nucleus. The paralysis of the face is then on the opposite side to that of the limbs. It is possible that an extensive unilateral lesion of the pons might cause paralysis of both sides of the face by destroying the nucleus of one facial nerve and the fibres of the other.

Again, association with hemiplegia of paralysis of the ocular muscles supplied by the *third nerve* shows that the seat of disease is the crus cerebri. The muscles in question are those affected on the side opposite to the paralysed arm and leg. An instance of this has been placed on record by Dr Hermann Weber ('Med.-Chir. Trans.,' vol. xxviii). A man, aged fifty-two, was attacked with paralysis of the right side of the body and of the muscles supplied by the left third nerve; he died after two months, and an oblong clot of blood was found in the left crus. Following Gubler, recent French writers have given a special name, that of "*Hémiplégie alterne*," to cases in which either the facial or the third nerve is affected on the side opposite to the limbs. "Crossed hemiplegia" is the English equivalent.

Sensation.—Statements that *anæsthesia* is absent in hemiplegia appear to have been based upon observations made on cases of long standing. There is every reason to believe that anæsthesia is generally present in recent cases, although its recognition may be difficult, or even impossible, in patients whose consciousness is much obscured. It is, however, far more transitory than motor paralysis, often passing off in a few days, and sometimes still earlier. In this respect lesions of the brain resemble those of the spinal cord and of the peripheral nerves (cf. pp. 403, 430). In slight cases of hemiplegia sensation is apparently unaffected, and even in the most profound it is never completely abolished. The hands and feet suffer more than the proximal part of the affected limbs, and the face least. But in exceptional cases, as Sir William Gull stated in his Gulstonian lectures (1849), anæsthesia is more marked than motor paralysis. In one case the writer noticed this in each of a series of hemiplegic attacks, some affecting the right and others the left side.

Subjective sensations of formication and numbness are frequently associated with partial anæsthesia, and sometimes there is a condition of hyperalgesia, or increased susceptibility to painful impressions. Sometimes, too,

spontaneous pains are experienced in the joints on the affected side, and particularly in the shoulder-joint.

Trophic changes.—Hemiplegic limbs are often reddened and warmer than those of the opposite side—a difference which is attributed to interference with the functions of the vaso-motor nerves. The inequality of temperature commonly amounts to something less than one degree Centigrade; after some months it ceases to exist. In some cases there is excessive sweating; sometimes slight œdema is discoverable. In a case at Guy's Hospital, dropsy (of renal origin) was limited to the arm and leg that were paralysed; and the late Dr Laycock, of Edinburgh, published examples of this curious fact. Charcot lays stress on the frequency of rapid sloughing of the skin over the gluteal muscles—an acute bedsore, as he terms it. One can hardly suppose that, in cases of this kind, there is much difference in the amount of pressure upon the two sides of the buttocks; and he regards the affection as a more or less direct effect of an interference with the nutrition of the tissues, caused by irritation of a particular region of the brain. Such bedsores are certainly very rare in cases of hemiplegia seen in this country; and equally so other trophic affections of the skin such as are noted in peripheral paralysis (p. 404).

As a rule contractions in the paralysed limbs by reflex action are less readily excited than on the healthy side; sometimes, but very seldom, more readily. In the latter case, some amount of tonic spasm is always present; the elbow is generally flexed and resists extension, and the fingers are bent in upon the palm of the hand. This condition was described by Todd under the name of "early rigidity," and was attributed by him to laceration of the surrounding healthy brain-substance by effused blood. This explanation has been adopted by most subsequent writers, although it has not been shown that there is more injury to the nervous tissues than in cases in which the muscles remain flaccid. So long as the muscles are in a state of early rigidity they do not waste; and subsequently they only undergo atrophy from disuse, without losing their faradic contractility, or showing any other signs of the reaction of degeneration. Rigidity only occasionally comes on early—more often it supervenes as a "late contraction" of the limbs, among the sequelæ of hemiplegia (p. 568).

Seat of the lesion.—It was once questioned whether paralysis of the arm and leg can be caused by a lesion limited to the *white substance* of the hemisphere or the *convolutions*, to the exclusion of the basal ganglia.

Mr Hutchinson has insisted on the frequent occurrence of hemiplegia when meningitis appears to be limited to one half of the brain, as so often happens after surgical injuries; but as a rule even extensive destruction of the cortex of the cerebrum is followed by no definite signs of paralysis, if it spares what is now known as the "motor area." The experiments of Fritsch and Hitzig, and those of Ferrier and Yeo, Schäfer and Horsley (to which we shall more fully refer in the next chapter), have shown that irritation of convolutions of this area causes movements in the opposite limbs; and also that lesion of these convolutions can produce a permanent paralysis. Cortical lesions, to use Dr Jackson's nomenclature, are not only "discharging," but also "destroying" lesions. Diseases of the ascending frontal and parietal convolutions, and of the adjacent parts of the frontal and of the superior parietal convolutions, may, if sufficiently extensive, give rise to permanent hemiplegia, although the corpus striatum remains perfectly healthy. Softening of this motor region of the brain is an occasional result

of obstruction of the Sylvian artery, beyond the origin of its "central" branches, whether by thrombosis or embolism (p. 553). The paralysis seems to be indistinguishable from that caused by a lesion of the basal ganglia; and it is followed by the consecutive degeneration of the spinal cord which will be described a little further on. On the other hand, similar affections of the sphenoidal, anterior frontal, and occipital regions cause no permanent hemiplegia.

We may therefore conclude that lesions of the motor gyri, and of the fibres which run thence through the corona radiata, may cause hemiplegia, just as lesions may which destroy the external capsule, the crura cerebri, or any other section of the motor tract.

As regards the lesions of the *basal ganglia*, Charcot maintains that, whenever a lesion is limited to one of the grey nuclei of the corpus striatum (the lenticulus or the cauda), the hemiplegia is always transitory, and very often incomplete; whereas if the internal capsule is involved it is commonly complete and persistent; but he impairs the force of this remark by adding that neither the nucleus caudatus nor the lenticulus is ever *wholly* destroyed without other parts being affected at the same time. He maintains that the limitation of paralysis to a single limb is never due to the fact that the morbid process is confined to a special seat within one of the ganglia: such limitation points to a lesion of the cortex. Dr Jackson agrees with this statement, and to explain it, supposes that "the whole corpus striatum is represented in miniature by every single part of it." Ferrier found that irritation of this part of the brain by faradic currents causes a general contraction of the muscles on the opposite side of the body, without its being possible to differentiate individual movements. But it is possible that, at least in the internal capsule, the fibres which belong to the upper limb may be distinguished from those that pass to the lower limb. We shall hereafter see that the cortical centre for the leg-muscles lies nearer the median plane than that for the arm-muscles; and, if there is a distinction of fibres in the internal capsule, those for the leg are probably situated further inwards and forwards than those for the arm. Since in cases of cerebral hæmorrhage the inner and fore part of the capsule often escapes laceration when the outer and hinder part is torn through, may not this be the reason why the upper limb so often remains powerless after the patient has regained the use of his lower limb, and why the arm sometimes becomes paralysed alone, while the leg escapes altogether?

Charcot believes that a broad line of distinction must be drawn between affections limited to the anterior two thirds of the internal capsule and those which involve its posterior third. In the former case there is no loss of sensation, in the latter there is hemianæsthesia, affecting the same side as the paralysis. He even believes, in opposition to some other authorities, that a lesion limited to the posterior third of the internal capsule may cause loss of sensation without any loss of power. The anæsthesia affects not only the limbs of one side, but also the corresponding half of the body and of the head. It includes insensibility to pain and to changes of temperature, as well as to tactile impressions; it extends to the deeper parts, and also to mucous surfaces; the patient feels nothing when his muscles are made to contract by the application of a current of electricity; and it affects the special senses of hearing and smell and taste.

Vision in hemiplegia.—In these and certain other cases hemiplegia impairs the sight; but there is difference of opinion as to the kind of imperfection

which results. According to Dr Hughlings Jackson this is lateral homologous hemiopia,* corresponding halves of each retina being affected in such a way that the patient is unable to see towards the paralysed side. In 1875 he had seen some thirteen cases of hemiplegia attended with the symptom in question. In one instance, in which the paralysis was on the left side, a *post-mortem* examination was made by Dr Gowers, who found a single lesion of the right thalamus, the posterior half of which was softened and of a greyish-yellow tint ('Lancet,' May, 1875). The hemiopia had been of the most marked description. The man had sometimes seen only half of a word, reading "land" for "midland," and remarking to his son that "Liver" was a queer name, when it really was "Oliver." Notwithstanding the statements of Mandelstamm, Michel, and others, it is probable that only the inner parts of the optic nerves decussate at the chiasma; and if so, we have a satisfactory explanation of this "homologous lateral hemiopia."

Charcot, however, denies that this affection of sight forms part of hemianæsthesia. On the contrary, he maintains that there is a "crossed amblyopia"—an impairment of vision in both halves of one eye—the one on the side which is deprived of sensation. He says that the acuteness of vision is often diminished by one half or even in a still higher degree. The visual field is generally narrowed on all sides, but for some colours the range is far more limited than for others. The first to be lost is violet; then, in succession, green, red, orange; the colours for which vision is retained longest are yellow and blue, but even they may at last be indistinguishable, so that every object appears of a brown colour, as if painted in sepia. Charcot quotes a case of Dr Bastian's, in which a lesion limited to one of the anterior corpora quadrigemina caused crossed amblyopia and not lateral hemiopia. If this view is correct, the only possible explanation seems to be that which he gives, namely, that there is a second decussation of the optic tracts for those fibres which failed to cross in the chiasma.

After-effects.—Hemiplegia is often recovered from, the patient gradually regaining the use of his limbs, until at length no difference can be made out between the two sides. As already remarked, the rule is for the leg to recover before the arm; the patient may be able to walk quite well with a crutch at a time when the hand is still motionless. Trousseau, however, relates two instances in each of which power was restored in the arm earlier than in the leg, and he maintains that when this is the case the prognosis is particularly unfavourable.

In many cases hemiplegia is permanent. The patient may for the rest of his life be unable to move any part of his arm, or he may regain power in it to a greater or less extent.

In almost every case the affected muscles pass, sooner or later, into a state of contraction, which is known as *late rigidity*. Bouchard found it absent in only one out of thirty-two cases that he examined. It generally consists in flexion of the joints; the elbow is bent at nearly a right angle, the wrist is pronated and flexed on the forearm, and the fingers are drawn in upon the palm of the hand, so that the nails sometimes penetrate the skin and produce painful ulcerations. Much more rarely a position of extension is assumed; the elbow may then be straight, the wrist may be thrown back, and the fingers may assume the griffin's-claw attitude which was de-

* These terms (half-sight or half-blindness) are now usually confined to lateral division of the field—whether homologous (or homonymous) or "crossed." The terms *hemiopia, hemianopia, hemianopsia*, are used indifferently to express the same condition (cf. p. 608).

scribed as occurring in progressive muscular atrophy (p. 497). The leg is less apt than the arm to become contracted, even when it remains paralysed; if at all, the hip- and the knee-joints are flexed, and the heel drawn up. This form of rigidity sets in so gradually that the exact period at which it begins cannot be determined. Bouchard speaks of a case in which it was present in a marked degree two months after the apoplectic attack which had caused the hemiplegia. Sometimes one can overcome the spasm by a little traction upon the affected parts; sometimes it resists the application of even a painful amount of force. The muscles are generally wasted, and feel like tight cords beneath the skin; but this atrophy is much later, and never so complete as that of anterior poliomyelitis.

Formerly it was supposed that late rigidity was caused either by the slow contraction of an apoplectic cyst, or by an inflammatory process in the surrounding brain-substance. But in 1866 Bouchard suggested, in the 'Archives Générales,' that it was probably an indication of the supervention of certain changes in the lower parts of the cerebro-spinal axis, which had been pointed out by Türck in 1853, and had been previously noticed by Cruveilhier as occurring after unilateral lesions of the brain. These changes are to some extent visible to the naked eye; the crus cerebri is smaller than on the healthy side, and presents a grey streak towards its inner edge; the corresponding half of the pons may be flattened; the anterior pyramid is of a greyish colour and wasted, so that the decussation of the pyramid is more conspicuous than usual. Below this point there is no marked alteration on the surface, but transverse sections of the spinal cord may show, in the lateral column of the side *opposite* to the lesion in the brain, a triangular grey patch, which gradually diminishes in size, but is traceable down to the lumbar enlargement. Or it may be only after hardening and staining that the change is discoverable by the microscope. It is found to consist, not only in a degeneration of the nerve-fibres which pass down the cord from the brain, but also in the formation of a delicate new connective tissue. In other words, there is descending sclerosis of a definite tract of the lateral column. Many nerve-fibres which probably arise from the spinal nuclei escape the degenerative process; and Bouchard's theory is that these unaltered nerve-fibres become irritated and cause the contracted state of the muscles. In support of it he adduces the analogous rigidity of the lower limbs which occurs when the upper part of the spinal cord is compressed.

Charcot believes that, once set up, the sclerosis may spread as an independent affection to the anterior grey cornua, causing the muscles to become again flaccid and to undergo a rapid degenerative atrophy; or to the posterior cornua, inducing partial anæsthesia; or, lastly, to the opposite lateral column, giving rise to a contraction of the other lower limb, as is supposed to have occurred in a case of Dr Bastian's.

More recently, however, Hitzig has proposed a different explanation of "late rigidity." He points out ('Arch. f. Psych.,' 1872) that prolonged rest is followed by a relaxation of the contracted muscles; that, for instance, after a night's sleep, the paralysed limbs are commonly flaccid and supple, and remain so until the patient begins to exert the opposite limbs in getting out of bed, or in some other way. Again, he has observed that voluntary efforts with the unaffected arm often cause an increase in the rigidity of the affected arm. In one of his cases, as soon as the patient was made to lift a heavy weight with his left hand, the thumb and forefinger of the paralysed right hand became quite stiff, although they had before been free from

spasm. He supposes that the contractions of hemiplegic limbs represent an excess of those co-ordinated movements in distant parts which naturally accompany every action of the body. He assumes that the spinal centres are in a state of irritation, and that, as a consequence, the movements in question become far more marked than under normal conditions. In further illustration of his meaning he instances the well-known fact that patients who are altogether unable to lift a hemiplegic arm by any voluntary effort sometimes see it move when they yawn or stretch themselves.

Whatever its explanation, "late rigidity" bears a close relation to certain forms of mobile spasm which may also present themselves in hemiplegic limbs, but more rarely, and only when the loss of voluntary power is incomplete. They vary greatly in character in different cases. Sometimes a more or less violent *tremor* is observed, either while the limb is at rest, or only when it is made to execute some voluntary effort. Charcot, for example, mentions an instance in which the act of carrying a glass to the mouth was attended with rhythmical movements, so that the liquid in it would be thrown in all directions. In other cases *spasms* are seen, which are more or less choreiform in character, so that Dr Weir Mitchell in 1874, and Charcot since, have spoken of a "post-hemiplegic chorea."

Lastly, some cases of chronic hemiplegia are attended with slow involuntary movements, principally affecting the thumb and fingers, and exactly like those described by Dr Hammond in 1871 under the term *athetosis*. The name (ἄθετος, without a fixed position) is intended to signify that the parts concerned in the spasm cannot be kept still. They are constantly moving, without any voluntary effort on the part of the patient. The fingers are alternately flexed and extended, with varying degrees of adduction or abduction, so as to give the hand a very odd appearance; and the toes may present similar changes of position. Cases of this kind have been described by Dr Allbutt and Dr Gairdner; and Dr Gowers has fully discussed "post-hemiplegic disorders of movement" in the 'Med.-Chir. Transactions' for 1876. Those which the writer has seen have been in young patients. Athetosis is often observed without antecedent hemiplegia.

APHASIA.*—Beside hemiplegia another symptom of cerebral obstruction or hæmorrhage is Aphasia, or loss of speech—the defect being of a special kind, and presenting characters which merit careful study.†

It is altogether distinct from a mere impairment of articulation, such as occurs in bulbar paralysis (p. 508), and often forms part of common cerebral hemiplegia (p. 562). These are due to imperfection in the movements of the tongue and palate, and the speech is more or less thick and difficult to be understood. But in aphasia, if the patient can utter a word at all, he commonly pronounces it quite clearly and dis-

* It has been called *alalia* and *aphemia;* but of these names the first is of doubtful authority, and the second would mean in Greek not loss of speech but loss of reputation. ἀφασία μ' ἔχει is a phrase used by Euripides, and in the form ἀμφασίη ἐπέων by Homer. To express want of power to write the term *agraphia* has been coined, and for want of ability to recognise written characters, *alexia*.

† "The inability to speak is sometimes owing not to the paralytic state of the organs of speech only, but to the utter loss of the knowledge of language and letters: which some have quickly regained and others have recovered by slow degrees, getting the use of the smaller words first, and being frequently unable to find the word they want and using another for it of a quite different meaning; as if it were a language which they had once known but by long disuse had almost forgotten. After an apoplectic state for several days, one person was forced to take some pains in order to learn again to write, having lost the ideas of all the letters except the initials of his two names."—*Heberden's Commentaries*.

tinctly. He may be altogether mute; or he may occasionally, when excited, ejaculate some oath, but it is impossible to get him to repeat it deliberately; or he may possess the power of saying two or three words or short sentences; these he uses sometimes correctly, but often in contradiction to his real meaning, and in answer to every question that is put to him. Thus Trousseau relates the case of a man named Paquet, who for four months said nothing but *tou-si-si, cousisi*, and who kept uttering these three syllables on all occasions, whether he was in a passion, or wished to express gratitude, or wanted to ask for or refuse something. Only, if he became very excited, he would sometimes say *sacon, sacon*—probably an abbreviation of the oath *sacré nom de Dieu*. Dr Broadbent had a patient who could scarcely say anything but *Oh, shameful! shameful!—Oh! pity, pity!* Of two celebrated cases recorded by Broca, one was that of a man who, possessing four words, *oui, non, trois*, and *toujours*, said *tan, tan*, to every question for twenty-one years. If there is a more extensive vocabulary the patient is very apt to use one word for another. Sometimes there is a likeness in sound between the two, as when *purging* takes the place of *perjury, pamphlet* of *camphor, dispersion* of *dispensary*; sometimes none, as when a patient of Dr William Ogle said *boat* instead of *tub*, or *two-shilling-piece* for *spectacles*.

A person who has known two or more languages may entirely lose the power of speaking in one of them, while he retains it in the others. Trousseau gives an instance of this in a Russian, who before his illness spoke French like a Parisian; and Bastian says that he has seen two similar instances, one being in a German who had long been resident in England.

Dr Ogle ('St George's Hosp. Rep.,' vol. ii) draws special attention to the fact that grammatical form is always observed; substantives are used in the place of substantives, verbs for verbs, numerals for numerals. M. Broca's patient employed *trois* to express any number, but corrected what he said by holding out the proper number of fingers at the same time. Dr Broadbent's patient possessed only one name for a locality, namely, Burlington, where she had lived as a child; and she used this for any place whatever.

Sometimes a patient who can utter only one or two words by himself is able to repeat a good many other words if he is prompted. Thus Trousseau relates the case of a man named Marcon, who could only say *Ma foi* and *Cré nom d'un cœur*, but who, when asked, "Are you from the Haute Loire?" replied *Haute Loire;* and then to the query, "What's your name?" echoed again *Haute Loire*. "Your profession?" *Haute Loire*. "But your name is Marcon?" *Yes, sir*. "What department do you come from?" *Marcon;* and so forth. We shall hereafter see, however, that such a case as this is not *mere* aphasia; nor should the name be applied to such a case as that recorded by Dr Bateman of a woman at the Salpêtrière, who, although she said nothing of her own accord, repeated everything that was said to her, and mimicked every gesture.

In 1889 we had for several months a patient in Mary Ward who had "common cerebral hemiplegia" of the right side with aphasia, and, excepting a word very occasionally ejaculated at random and immediately forgotten again, her only language was the repetition of the syllables *ten-ten*, or sometimes with a rather more open vowel sound, which must have come very near that of Broca's patient. She seemed intelligent, and was cheerful, taking interest in the slow and gradual recovery of her paralysed muscles; and it was curious to see how perfectly by help of her one word, uttered with perpetual variety of accent and intonation, she was able to convey acquiescence

and negation, pleasure and pain, entreaty, remonstrance, and gratitude. Much pains were taken to teach her fresh words; but though she learnt one for a time, she quickly lost it again; and when after several months she left the hospital, able to walk with support, and having some power over her arm, she went out repeating *ten-ten*, with a new meaning of farewell.

Agraphia.—In some, but not in all, cases of aphasia the patient loses the power of expressing himself in other ways as well as in speech. The person who is aphasic is sometimes able to make all his thoughts known with his pen. Trousseau relates the case of a carrier belonging to the Paris Halles, who came into the consulting room making signs that he could not speak, and handed in a note in which the history of his illness was detailed. He had written it himself, and it was perfectly well worded. A few days previously he had suddenly lost his senses, and remained unconscious for nearly an hour. When he came to he had no paralysis, but he could not articulate a single word. In the course of five or six weeks he completely recovered; but what was remarkable was that during the whole course of the disease he could manage all his affairs by substituting writing for speech. Such cases are very exceptional. As we shall presently see, paralysis of the right hand is very often present in those who have aphasia; and of course it is then difficult for the patient to write. One way of ascertaining whether the power of combining letters to form words is preserved is to give such a person the loose wooden letters that children play with, asking him to spell his name or to put together a sentence. He may be quite incapable of doing so; indeed, he may not even be able to pick out the letters that make up the one or two words that he is perhaps able to articulate (*alexia*). Trousseau's patient, for instance, whose one word was *oui*, could not point to the letters *o*, *u*, *i*, in the title-page of a large quarto volume.

The impairment of power to write is sometimes marked, when speech is but little affected. Dr Jackson records the case of a partially aphasic patient who could talk pretty well, although she made mistakes in speaking, and called her children by wrong names; but when told to sign her name she wrote *Sunnil Sielaa Satreni*, in which there was no resemblance to the real name either in sound or spelling; and when told to write her address she put down *Sunesr met ts mer tina—lain.* We shall presently see that if there is much impairment of the intelligence the value of agraphia as a symptom is much diminished; but both Trousseau's patient and Jackson's appeared to have their full mental faculties.

Again, it has been shown that in some cases of aphasia the memory of *other modes of expression* is lost, beside spoken and written language. Trousseau says that a patient may be unable to imitate the face of a person who is crying, although when he feels grief the expression of his countenance shows it clearly enough. In the case of Paquet, who said nothing but *Cousisi*, Trousseau first held out his hands and moved his fingers, as though playing the clarionet, and asked this man to do the same. Paquet immediately executed the same movements with perfect precision; and when asked whether he knew that the attitude was that of a clarionet player he would assent by nodding his head. Yet when told, a few minutes afterwards, to place himself in the same attitude, he seemed to think, and often was unable to do it.

An aphasic patient, whose case was carefully studied by Dr Scoresby Jackson ('Edin. Med. Jour.,' 1867) was totally unable to play the piano.

He put himself in the proper position, and placed his fingers on the keys, but he could not play a single bar, not even of a piece of music with which he had been familiar before his illness; yet he could hum the same tune pretty well. He played draughts with skill; and Paquet also could play backgammon and dominoes perfectly, and would cheat when he found himself losing.

Amnesia.—It is important to notice that the very words which an aphasic patient is unable to utter are perfectly understood by him when spoken by another person. This, indeed, is but an illustration of a broad distinction which is traceable throughout the faculty of speech. A child learns the meaning of words addressed to it by others long before it can itself speak. A person partially acquainted with a foreign tongue recognises many words, if spoken distinctly by anyone else, which he would have been unable to call from his memory if he wanted them in conversation. Nay, we all of us understand the meaning of many English words when we hear them which we never use ourselves. Adopting terms used by Dr Moxon, we may say that there is a great difference between "incoming" and "outgoing" language; or, following Dr Broadbent, that words are to be considered in two distinct aspects: first as "intellectual symbols," and then as "motor processes." In ordinary aphasia and agraphia it is the *outgoing language* and *motor processes* that are interfered with; in amnesia and alexia it is the *incoming language* and *perception* of intellectual symbols.

The same distinction is denoted by Wernicke's terms: *motor* (ordinary) *aphasia*, including agraphia, and *sensory aphasia*, including alexia; and by Charcot's "verbal and graphic amnesia" which are represented in English by "word-deafness" and "word-blindness" respectively.

It may be that perception of the meaning of the words spoken by others, and uttering words for one's self, are functions of different parts of the brain. Or, again, it may be that both "incoming" and "outgoing" language have their seat in the same locality, but that the latter requires for its execution some subordinate nervous centres which have nothing to do with the former. The second of these hypotheses was defended with great ability by Dr Broadbent in the 'Med.-Chir. Transactions' for 1872.

The local lesion.—It has now been established that aphasia—including agraphia—is almost invariably dependent upon a lesion of the *left side* of the brain. This was assumed by Broca as the result of a case which he published in the 'Bulletin de la Société Anatomique' for 1861.*

This association, though previously completely overlooked, is beyond question, and can at any time be determined by clinical observation. If a number of hemiplegic patients be taken, it will always be found that many of those in whom the paralysis is on the right side are speechless, whereas probably every one among them whose left arm and leg are paralysed will be able to articulate as distinctly as is compatible with the condition of the tongue and lips. Moreover, in much rarer cases, aphasia will be found to exist without any paralysis, and the lesion is almost invariably in the left side of the brain. Lastly, to complete the argument, the exceptions themselves illustrate the rule, for in left-handed persons (whose right hemisphere takes the precedence in movements which the left does in the rest

* It was stated nearly thirty years after the event that Dr Marc Dax, of Sommières, read a paper on the subject before a Medical Congress at Montpellier in 1836, but the memoir has never been seen since. Its title was "Lésion de la moitié gauche de l'encéphale coincidant avec l'oubli des signes de la pensée." Certainly no one, either in Paris or in London, was acquainted with the views of M. Dax when Broca published his paper.

of mankind*) loss of speech goes with paralysis of the left limbs, and not with that of the right limbs; or, in other words, it depends upon disease of the right hemisphere instead of the left. Examples of this association have been recorded by Dr Jackson ('Med. Times and Gaz.,' 1866), Dr John Ogle ('Lancet,' 1868), and Dr Wadham ('St George's Hospital Reports,' 1869), and two well-marked cases have occurred in Guy's Hospital.

Further, it was proved by Broca that aphasia is caused by lesions of a particular part of the surface of the brain on the left side. Bouillaud was long ago led by clinical observation to connect the faculty of language with the *anterior lobes* of the brain, and, indeed, Gall had previously suggested the same localisation.†

But it was not until a second case of M. Broca's was published, in November, 1861, that anything like precision of localisation was arrived at in regard to loss of speech. The case in question is that of a man named Lelong, aged 84, who after an attack of apoplexy lost the power of uttering words, with the exception of four, although he knew all that was said to him, and could make himself understood by gestures. He died at the end of a year of a fracture of the femur. At the autopsy the posterior third of the second and of the third left frontal convolutions were found to have been destroyed by softening, their place being occupied by a secondary hæmorrhagic cyst.

Ever since, the *third left frontal* has been known as Broca's convolution, and it is now admitted that aphasia is always dependent upon a lesion involving that region, if we limit it to the posterior part of the third left frontal gyrus, and extend it to the back of the second frontal and adjacent parts of the ascending frontal and *gyri operti*.

In the first place, no disease of the corpus striatum, or even of the white substance outside it, is capable of causing loss of speech. The general accuracy of this assertion is proved by the fact that cerebral hæmorrhage, in the position in which it usually occurs, leaves the speech unimpaired. In 1876 Dr Broadbent was able to say ('Brit. Med. Journ.,' i, p. 436) that he knew of no case on record in which lesion of the corpus striatum alone had given rise to this symptom. At first sight such a fact might seem inexplicable, since it is difficult to see how any effect can be produced by destruction of a convolution which may not equally follow the division of those conducting fibres which connect it with the basal ganglia, or even with the spinal centres. No writer appears to have faced this difficulty except Dr Broadbent himself. He believes that there are two distinct routes by which impulses pass from Broca's convolution to the nerve-nuclei in the pons, medulla oblongata, and medulla spinalis. One is the straight path through the left corpus striatum, the other is by commissural fibres which go to the third frontal convolution on the opposite side, and thence down through the right corpus striatum. So long as either of these routes remains open, speech is possible; it being of course assumed that the nuclei on opposite sides are so closely associated together by cross connections as

* The relation of the left side of the brain to movement and speech was discussed by the writer in the 'Guy's Hosp. Reports' for 1870, and more fully and satisfactorily by Dr Wm. Ogle in a paper on 'Dextral Pre-eminence' ('Med.-Chir. Trans.,' 1871.)
